The respiroviruses comprise a genus within the *Paramyxoviridae* family whose members include the human pathogens parainfluenza virus types 1 and 3, bovine parainfluenza virus, *Sendai virus* (a mouse pathogen), and a number of other less-studied members, including murine parainfluenza virus type 1 and simian respirovirus 10. These viruses have features that distinguish them from other members of the *Paramyxovirinae*. They all possess both hemagglutinating and neuraminidase activities on their receptor-binding protein, and all have the ability to encode a nonstructural C protein. Like all other members of the *Paramyxovirinae*, these viruses, although pleimorphic, are roughly spherical in shape, are approximately 150-400 nm in diameter and possess a lipid envelope composed of host cell lipids and viral glycoproteins that is derived from the plasma membrane of the host cell during budding. Figure 1 shows a schematic diagram of a representative respirovirus particle. All contain a negative-strand nonsegmented single-stranded RNA genome that is encapsidated by the viral nucleocapsid protein and forms a helical nucleocapsid (Choppin and Compans 1975). The viral RNA of each is approximately 15 500 nucleotides in length. Like all negative-strand RNA viruses, the respiroviruses encode and package an RNA-dependent RNA polymerase in the virion particles. The polymerase activity is only manifest on the RNA/NP helical nucleocapsid template and is attributed entirely to two viral proteins, L and P. There are approximately 50 P proteins and 300 L proteins per virion nucleocapsid (Lamb et al. 1976).

The negative-strand RNA genome of all respiroviruses contains six genes arranged in the order 3′-NP–P/V/C–M–F–HN–L-5′. The *NP* gene encodes the nucleocapsid protein that binds to the viral genome and antigenome during RNA synthesis, forming the characteristic helical nucleocapsids. The *P* gene of all respiroviruses encodes the phosphoprotein P (a subunit of the viral polymerase), another protein termed C, and for several members (Sendai and bovine parainfluenza type 3) also encodes a V protein via nontemplated nucleotide addition to the mRNA, a process referred to as RNA editing (see below). The *M* gene encodes a nonglycosylated membrane-associated protein, termed membrane or matrix protein. The M protein binds both to viral nucleocapsids and to viral glycoproteins that have been inserted into the host cell membrane, playing

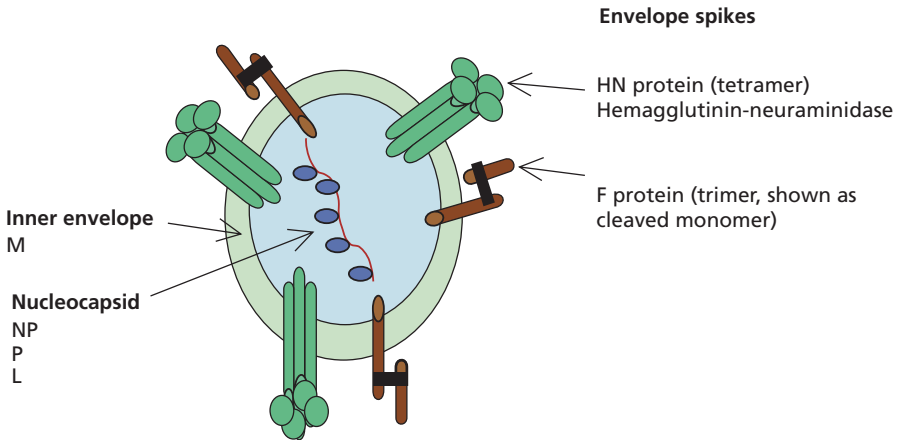

Figure 1 *Schematic diagram of a parainfluenza virus*

a role in virus assembly. The M protein also lends structure to the viral envelope, forming a protein layer between the lipid envelope and the helical nucleocapsid within. The F and HN genes encode the two integral membrane glycoproteins, the fusion (F) protein and the hemagglutinin-neuraminidase (HN). The F glycoprotein mediates fusion between the viral and host-cell membranes during infection, while the HN glycoprotein, possessing both receptor-binding and receptor-destroying activities (i.e. hemagglutinating and neuraminidase functions), is responsible for attachment of the virus particle to receptors on the cell, interaction with the F protein to mediate fusion between the viral and cell membranes, and release of progeny virus particles from infected cells. The *L* gene, comprising approximately 50 percent of the coding capacity of the virus, encodes the L protein, the catalytic subunit of the viral RNA polymerase.

Viral entry and membrane fusion: the roles of the surface glycoproteins

A characteristic feature of paramyxovirus infection in cell culture is the induction of cell fusion at neutral pH, resulting in the formation of syncytia. While several elements of the fusion process have been extensively studied, there remains much to learn about the precise role of each of the surface glycoproteins and the critical determinants of fusion. Several basic features of the glycoproteins are shown in Figure 2. Infection of cells by respiroviruses is initiated by attachment of the virus to the host cell through interaction of the HN glycoprotein with a neuraminic acid-containing molecule on the host cell surface. The fusion glycoprotein F is synthesized as a single polypeptide chain (F0) that forms a trimer before being cleaved by host-cell proteases to yield a membrane-distal (F2) and membrane-anchored subunit (F1). The new N-terminal region of the membrane-anchored subunit F1, termed the fusion peptide, contains hydrophobic residues that insert into target membranes during fusion at neutral pH (reviewed in Hernandez et al. (1996)). Penetration and uncoating of the virus occur by fusion of the viral envelope with the plasma membrane of the cell, resulting in the release of the viral nucleocapsid into the cytoplasm. Infection also results in fusion between cells, which involves the interaction of F and HN proteins expressed on the surface of an infected cell with the membrane of an adjacent uninfected cell. The role of the receptor binding surface glycoprotein, HN, in this process has been the focus of much investigation in recent years, and is discussed in detail below.

THE HEMAGGLUTININ-NEURAMINIDASE

The HN proteins are type II transmembrane glycoproteins, oriented such that their NH_2 termini extend into the cytoplasm while the C termini are extracellular. The neuraminidase activity of HN is important for removing sialic acid residues from the viral and cellular surfaces to prevent self-aggregation and to allow for the release of newly formed virus. HN is present on the cell surface as a homotetramer composed of disulfide-linked homodimers (Markwell and Fox 1980; Thompson et al. 1988; Ng et al. 1989; Russell et al. 1994). The molecule contains a cytoplasmic domain, a membrane-spanning region, a stalk region, and a globular head. The membrane distal globular head region contains the sialic acid-binding site, which mediates attachment to sialic acid-containing receptor molecules on the cell surface to initiate infection. The recent publication of a suite of crystal structures of Newcastle disease virus (NDV) HN (Zaitsev et al. 2004) and parainfluenza virus type 3 HN (Lawrence et al. 2004) (shown in Figure 3 complexed with sialic acid) demonstrate the locations of the active site residue (T193 for parainfluenza virus type 3 HN) on the globular head of the molecule. These structures, when taken together with experimental data about the HN, promise to reveal much about the functions of HN and its interaction with F (see below).

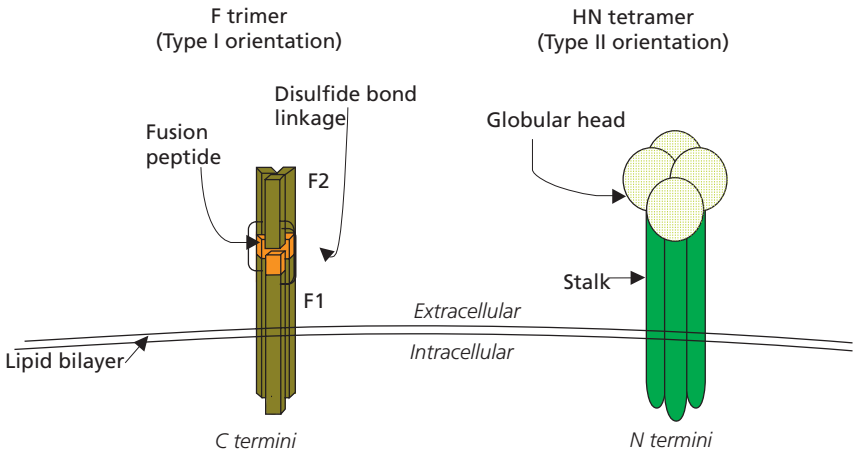

Figure 2 *F (fusion) and HN (receptor-binding) proteins*

RECEPTOR MOLECULES FOR PARAINFLUENZA VIRUSES

The receptors for parainfluenza viruses are known to be sialoglycoconjugates based upon their destruction by neuraminidases. Beyond this general classification, little is known. For human parainfluenza virus type 3 (HPIV-3) and other respiroviruses, the virus appears to be specific in its use of receptors (Moscona and Peluso 1996; Suzuki et al. 2001) in that it cannot make use of all potential sialic acid-containing surface molecules. For Sendai virus, specific gangliosides have been shown to be capable of functioning as receptors. Sendai virus binds to and fuses with liposomes containing gangliosides (Haywood 1974; Haywood and Boyer 1982), and three gangliosides belonging to the same family were shown to function as receptors for this virus in cultured cells (Markwell et al. 1981). It was shown that the minimal structure recognized by Sendai virus is NeuAcα2,3Gal. While glycolipids have been shown to function in initiating infection by Sendai virus, cell surface glycoproteins also contain the NeuAcα2,3Gal sequence as one possible type of carbohydrate modification. A number of studies have used sialidases to destroy receptors, followed by sialyltransferases to resialylate the cell surface in order to determine the important sialic acid component of the receptor (Paulson et al. 1979; Markwell and Paulson 1980), but these experiments do not determine whether the biologically important glycoconjugate is a lipid or a protein since these enzymes can use either glycolipids or glycoproteins as substrates. In addition, although various studies with Sendai virus have assessed binding to erythrocytes or liposomes (Haywood 1974; Suzuki et al. 1985), it remains unclear which molecules are actually used on target cells. For example, Sendai virus was shown to bind to heparin, and this binding inhibited Sendai fusion with erythrocyte ghosts or liposomes (Ohki et al. 1992; Zschornig et al. 1993). Recently, it was suggested that HPIV-3 can utilize heparan sulfate (HS) during the cell entry process (Bose and Banerjee 2002). HPIV-3 interacted with HS-agarose in vitro, and cellular entry was reduced if HPIV-3 was preincubated with soluble HS or if target cells were treated with heparinase to remove cell surface HS. However, inhibition was incomplete, suggesting at least that additional cell surface molecules

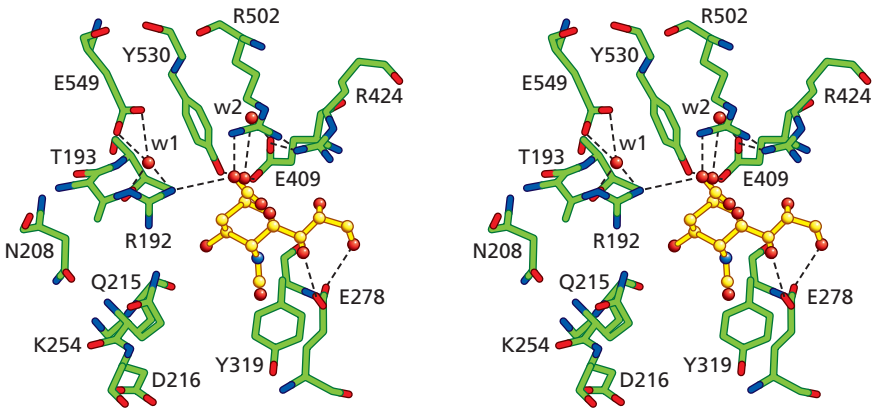

Figure 3 *HN active site (parainfluenza type 3) complexed with sialic acid (from Lawrence et al. 2004).*

are required. It is not known whether HS interacts with the HPIV-3 HN or F proteins. It is clear that HS is not used as the primary entry receptor, but it is possible that HS plays a secondary role and augments the efficiency of entry for HPIV-3, as well as Sendai viruses. While paramyxoviruses have many biological properties in common, several lines of investigation have now highlighted important differences between viruses of this family in regard to the viral entry and fusion processes, and it remains important to identify target receptors used by respiroviruses.

THE DUAL FUNCTION OF THE HN MOLECULES: A BALANCE OF ACTIVITIES

Unlike influenza viruses, in which separate surface glycoproteins are responsible for the neuraminidase and receptor-binding activities, the respirovirus HN is a dual function molecule. The existence of separate sites for the receptor binding and neuraminidase functions of the HN molecule has been debated extensively. Studies performed in various paramyxovirus family members with mutations in different HN residues have addressed this question by attempting to ascribe functional roles to these residues. The varied results failed to elucidate definitively whether the dual HN functions reside in the same or distinct sites. In studies of HPIV-3, both the neuraminidase and receptor binding activity of HN was inhibited by sialic acid analogues such as DANA (Levin Perlman et al. 1999) and 4-GU-DANA (Greengard et al. 2000). Passaging of HPIV-3 in the presence of 4-GU-DANA yielded an HN variant, ZM1, in which an alteration of residue 193 increased the receptor binding, as well as the neuraminidase activity, and conferred 4-GU-DANA resistance for both activities (Murrell et al. 2003). Analysis of this (4-GU-DANA-resistant) variant ZM1 supported the possibility of a single site capable of affecting both binding and enzymatic properties (Murrell et al. 2003) and the presence of a single, multifunctional site on HPIV-3 HN therefore appeared likely. A single site was also implicated in a study of bovine parainfluenza virus 3 (BPIV3) in which residue 193, the HPIV-3 193 correlate, affected both hemagglutinating and neuraminidase activities and thus suggested a single site (Shioda et al. 1988). Several studies employing monoclonal antibodies to select for Sendai virus escape variants postulated an HN with dual sites (Portner 1981; Portner et al. 1987; Thompson and Portner 1987; Gorman et al. 1990; Lyn et al. 1991). Initial crystallographic studies suggested that a single site on NDV HN was responsible for both activities (Crennell et al. 2000). However, a more recent study has identified an additional potential NDV HN receptor-binding site (Zaitsev et al. 2004). Recently, a third function of HN has become clear. Upon binding to receptor, parainfluenza HN plays a critical role in 'triggering' F to undergo its final conformational alteration that permits fusion (Porotto et al. 2003). This is discussed in detail below.

For influenza virus, the balance of NA and HA activities is important for the retention of in vivo viability. If virus binds receptor avidly, then entry will be efficient, while release will be hindered resulting in loss of viability. If receptor binding is reduced drastically, then entry of the virus is compromised resulting in a similar loss of viability. It is the balance of these two functions that determines the functional characteristics of influenza virus, including its ability to escape inhibition by a molecule like 4-GU-DANA. Balance of the dual functions of HN is also important for the functional characteristics of HPIV-3, even though the distinct biological activities of receptor binding and receptor destruction reside on a single molecule. For example, the fusogenic HPIV-3 variant C-0 incurred a single amino acid change that altered only its receptor binding affinity (Moscona and Peluso 1993). Another fusogenic HPIV-3 variant, C-28, possessed a single alteration that reduced the neuraminidase-specific activity while sparing its receptor binding affinity (Huberman et al. 1995). However, both variants exhibit similar highly fusogenic phenotypes distinct from wildtype HPIV-3. Thus, it is possible to affect HN functions separately, and, similar to influenza virus, the balance of binding and release influences the outcome of HPIV-3 infection. It is likely that the quantitative relationship between HN's receptor-binding and receptor-destroying functions determines the outcome of infection by parainfluenza viruses. It has been shown that virion release depends on this balance (Porotto et al. 2001). The ability of HN to trigger F to fuse (see below) is intimately related to HN's receptor bound state. Therefore, the balance between HN's two functions – binding and release from receptor – ultimately determines the third key HN function, the promotion of fusion, and thus viral entry (Porotto et al. 2001, 2003). Figure 4 presents a model of the several points of HN action in the cell during infection.

VIRAL INTERFERENCE

Viral interference is characterized by resistance of infected cells to infection by a challenge virus. This type of interference has been documented for several paramyxoviruses, including Sendai virus (Kimura et al. 1976) and NDV (Bratt and Rubin 1967a, b; Bratt and Rubin 1968) and was presumed to be due to the destruction of viral receptors by the viral neuraminidase. For HPIV-3, it was shown that interference is mediated by HN, and that the HN-mediated interference effect can be attributed to the presence of an active neuraminidase enzyme activity (Horga et al. 2000), indicating that the mechanism for attachment interference by a paramyxovirus is attributable to the viral neuraminidase.

THE FUSION PROTEIN

The fusion protein F, shown schematically in Figure 5, is important in the fusion process of all

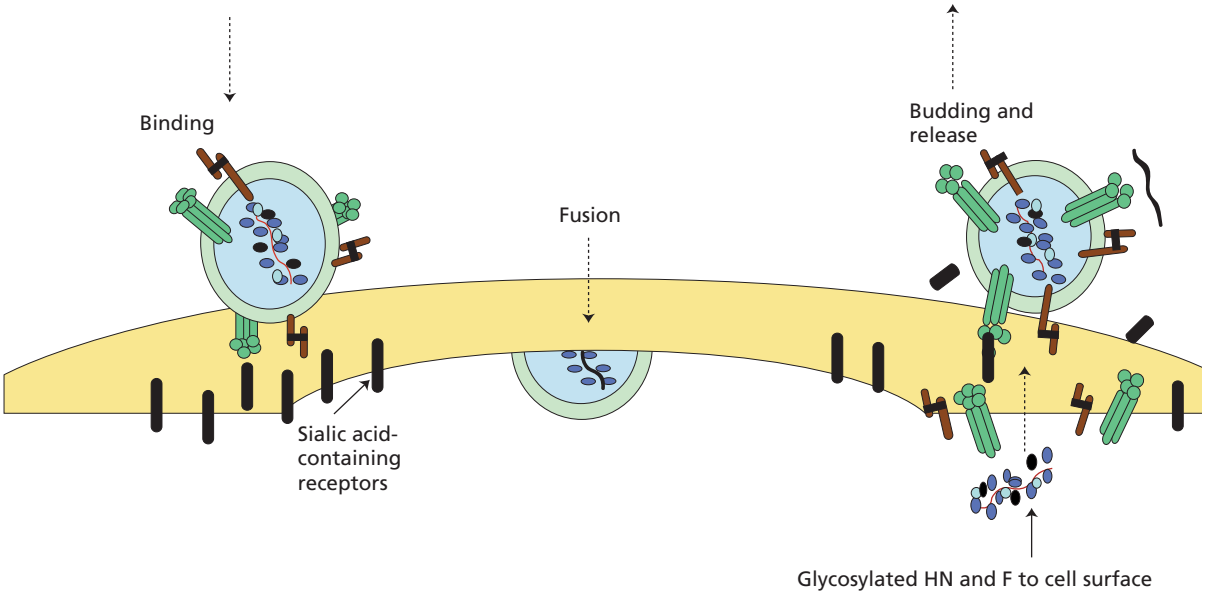

Figure 4 *Points of HN action*

paramyxoviruses (Lamb 1993; Plemper et al. 2003). The F proteins are type I integral membrane glycoproteins, synthesized as the inactive precursor F0, which trimerizes in the endoplasmic reticulum (Dutch et al. 2000). F0 is cleaved by a host cell protease during its transit to the cell surface to produce the active protein, which consists of two disulfide-linked subunits, F1 and F2 (Homma and Ouchi 1973; Scheid and Choppin 1974). After this cleavage, a new hydrophobic N-terminus is exposed. This is the fusion peptide, the region directly involved in mediating fusion of the viral envelope to the plasma membrane of the host cell. The F protein cleavage sites contain multiple basic amino acids, and are cleaved in the trans-Golgi network by subtilisin-like endoproteases, furin and Kex2, with the sequence specificity of R–X–K/R–R. For several paramyxoviruses (e.g. Sendai, NDV) the efficiency of cleavage has been shown to directly correlate with host range and tissue tropism of the virus, with greater 'cleavability' associated with virulence (Nagai et al. 1976, 1979; Nagai and Klenk 1977; Garten et al. 1980, 1992; Pritzer et al. 1990; Tashiro et al. 1990, 1992; Klenk and Garten 1994; Ortmann et al. 1994). It is also is likely that, by playing a role in determining the

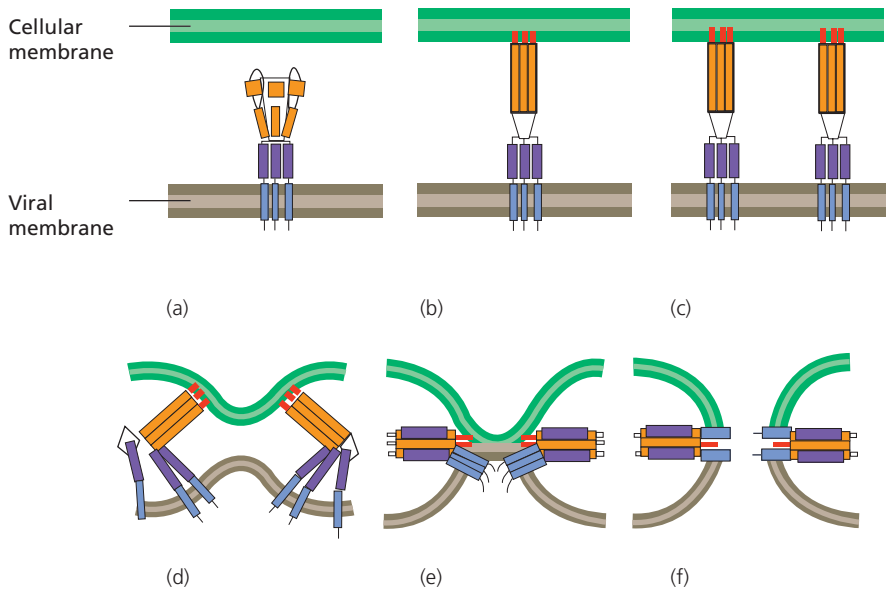

Figure 5 *Schematic general model of fusion protein-mediated membrane fusion (from Jardetzky and Lamb 2004)*

budding efficiency from different cell types, the F protein affects cell and host tropism for the parainfluenza viruses (Okada et al. 1998). F proteins contain a hydrophobic domain (stop transfer signal) at the C terminus that anchors the protein in the membrane. It has been shown that the fusion activity of F is regulated in part by the cytoplasmic domain of the protein (Dutch and Lamb 2001; Tong et al. 2002; Seth et al. 2003).

FUSION MECHANISMS AND THE ACTIVATION OF F PROTEIN

The available data on viral fusion proteins of paramyxoviruses indicate that before initiating the fusion process, fusion proteins remain in a metastable state, which requires a trigger of some sort to induce the conformational change that leads to exposure of the fusion peptide (for a review, see Jardetzky and Lamb (2004)). A second 'activation' step is required for fusion readiness. For the parainfluenza viruses, this step requires interaction of the HN protein with its receptor. The triggering of the conformational change from a metastable fusion protein to a fusion-active state was initially elucidated for influenza HA (Carr and Kim 1993; Chen et al. 1998). The mechanism of this fusion activation in paramyxovirus F molecules is thought to have analogies to the influenza HA. The possibility of a common process is supported by the fact that the post-fusion conformation of HA, as well as several paramyxovirus F proteins, consist of a six-helix coiled-coil formed by three heterodimers of two heptad repeat (HR) regions (HRA and HRB). In this 'final' structure, the fusion peptide and the transmembrane domain are brought into proximity, allowing for membrane fusion (Skehel and Wiley 1998). For paramyxoviral F proteins, as well, the final F structure in which the fusion peptide is exposed requires formation of this stable six-helix structure leading to membrane merger (Baker et al. 1999). A schematic diagram of the process, from a recent review by Jardetsky and Lamb, is shown in Figure 5. Step (a) shows the metastable fusion protein; in (b) and (c) the fusion peptides are released and inserted into the target membrane. The proteins refold into a trimeric hairpin shape (d) and in (e) a helical coiled-coil rod forms next to the fusion peptide and refolding relocates the fusion peptides and transmembrane regions to the same end of this coiled coil, with the free energy that results from this step bringing the membranes closer together. With the completion of refolding, the most stable form of the protein is formed (f) and fusion is complete (Jardetzky and Lamb 2004).

The paramyxovirus F1 ectodomain contains two conserved heptad repeat (HR) regions, designated HRA and HRB, located near the fusion peptide and the transmembrane domains. Peptides derived from the HRA and HRB regions have been used to inhibit fusion intermediates of F (Lamb and Kolakofsky 2001) and thereby to elucidate the mechanism whereby F mediates fusion. The HRA and HRB peptides are thought to inhibit fusion by preventing the F protein from forming the helical bundles required for fusion.

While for influenza virus the 'trigger' leading to conformational change of the fusion protein is the low pH of the endosome, for paramyxoviruses, which fuse at neutral pH at the cell surface, this trigger is likely to be HN-receptor binding. While the F protein is the molecule directly responsible for fusion of the lipid bilayers, the receptor-binding protein HN has also been shown to be essential for cell fusion mediated by HPIV. Interaction of HN with its receptor is required in order for F to promote membrane fusion during viral infection (Moscona and Peluso 1991; Horvath et al. 1992; Lamb 1993; Bagai and Lamb 1995). It has been proposed that upon binding sialic acid receptor, HN undergoes a receptor-induced conformational change, which in turn triggers a conformational change in F that allows fusion to occur (Lamb 1993; Porotto et al. 2003). Lamb recently showed that coexpression of HN with F of SV5 results in F protein susceptibility to HRA peptide inhibition, supporting the notion that HN binding to receptor induces a conformational change in F (Russell et al. 2001).

The triggering mechanism of paramyxovirus F at neutral pH is an area of active investigation. Lamb has shown that the free energy generated by the formation of the coiled-coil structure in F is the driving force for membrane fusion (Russell et al. 2001). There is evidence that the HN and F proteins interact (Tanabayashi and Compans 1996; Yao et al. 1997; Tong and Compans 1999). Recent work has supported the notion that HN interacts specifically with F protein to enable F to mediate fusion, and has generated models for this process. While, as above, co-expression of SV5 HN with F resulted in F protein susceptibility to HRA-region peptide inhibition, suggesting that HN binding to receptor induces a conformational change in F, the F protein fusion intermediate that was inhibited by the HRB peptide bound RBC independently of HN (or after HN had already exerted its action on F), and is likely to be the prehairpin stage of F immediately preceding membrane merger (Russell et al. 2001). The HRB peptide (corresponding to the region near the TM domain) binds F after the activation has already occurred, and F has been triggered to insert in the target membrane (and fusion at that point is independent of HN). The HN–receptor interaction is thus likely to be required for F protein function quite early in the triggering process. Many of the steps in the fusion and entry process remain to be understood. In particular, why is there a requirement for HN receptor binding, in order to initiate fusion promotion? What is the relationship between the 'docking' function of HN and its role in fusion promotion? A current model for paramyxovirus

glycoprotein function proposes that HN attachment to receptor leads to interaction, which then triggers F (Russell et al. 2001). Alternatively an HN–F complex may form during trafficking to the surface, and HN attachment may lead to a conformational change in HN with a resulting release of F's fusion peptide (Russell et al. 2001). Models of possible mechanisms whereby binding of HN to receptor may contribute to activation of F are illustrated in Figure 6. The role of cell membrane constituents, including lipids and lipid rafts, in the organization of the glycoproteins for the fusion and entry process, and the potential role of cytoskeletal molecules in this process (Pastey et al. 1999; Pastey et al. 2000), remain to be clarified.

Primary transcription and replication

ROLES OF NONCODING SEQUENCES

As mentioned in Classification and structure, all respiroviruses contain six genes arranged in the order 3′-NP–P/V/C–M–F–HN–L-5′. In addition to the six mRNA-encoding portions of the genomic RNA, there are extragenic nucleotide sequences that control polymerase function. At the ends of the genome are short transcribed noncoding sequences that serve as polymerase-binding sites, as well as encapsidation signals. These sequences are called leader and antileader (or trailer) for the 3′ and 5′ ends, respectively. The leader RNA contains the signal to initiate binding of the NP protein to a nascent RNA product, and the promoter, or viral RNA polymerase binding site, on the negative-strand RNA template. The antileader (trailer) serves a similar dual function during the second stage of genome RNA replication, when full-length encapsidated plus-stranded RNA-containing nucleocapsids (antigenomes) are copied into progeny negative-strand RNA-containing nucleocapsids that are then packaged into progeny virions.

At the start of each gene, there are conserved sequences of ten nucleotides in length (3′-UCCRXXUUXC). Between each gene there is a trinucleotide sequence (3′-GYY) and at the end of each gene 11 conserved bases (3′-UXXUXXUUUUU), where R is a purine, Y is a pyrimidine, and X indicates no consensus (Kolakofsky et al. 1998). These sequences are believed to signal initiation of transcription and polyadenylation and termination of the mRNA. Except for the small number of intergenic nucleotides, all of the RNA of the viral genome is transcribed into either mRNA or leader RNAs, and most of the transcribed RNA is translated into viral proteins.

THE REPLICATION CYCLE

Replication of the virus occurs exclusively in the cytoplasm. Infecting virions fuse with the plasma membrane of the cell, releasing the viral nucleocapsid into the cytoplasm. The nucleocapsid contains the genome RNA in tight association with the viral NP protein, in the form an RNAse-resistant helical structure that is stable in

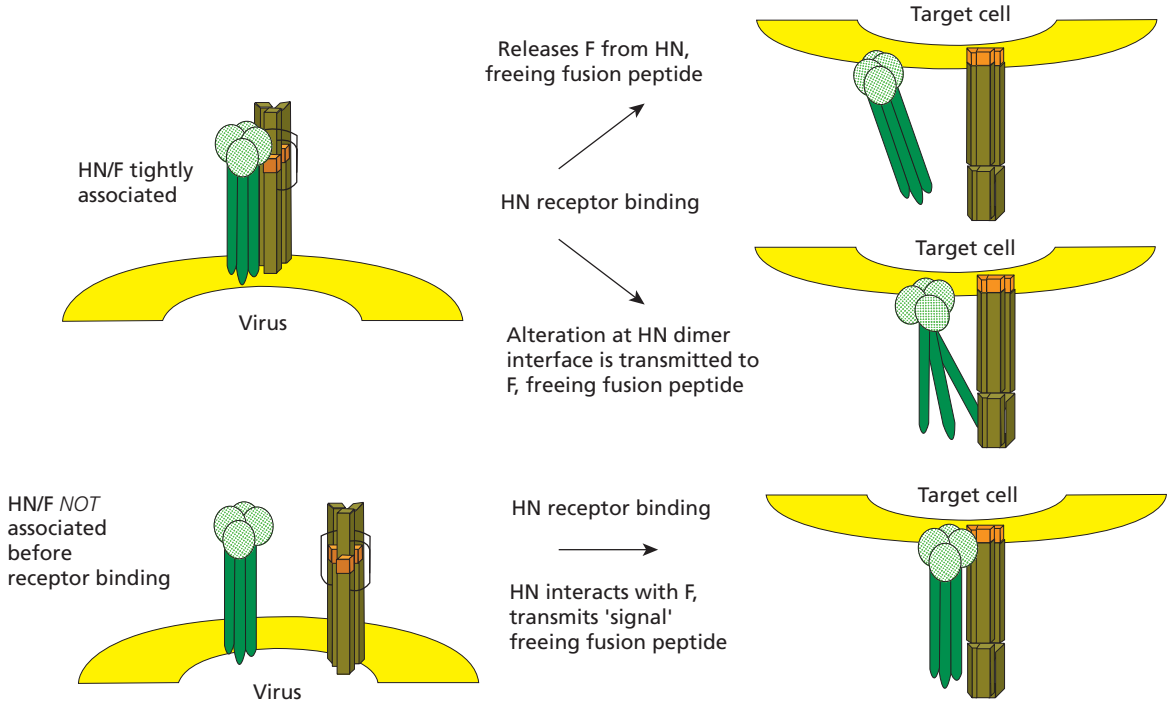

Figure 6 *Models for the role of HN–receptor interaction in F activation*

cesium chloride and readily visualized in the electron microscope. This RNA/protein complex is the template for both transcription and genome RNA replication, and there is no evidence that the structure uncoats further. Figure 7 represents this process, showing schematically that: (1) transcription and genome RNA replication both occur using the viral RNP nucleocapsid as a template; (2) during transcription multiple subgenomic mRNA molecules are made; (3) each subgenomic mRNA molecule is capped, methylated, and polyadenylated; and (4) during genome replication a full-length plus-stranded copy is made and encapsidated. This full-length positive-sense strand is the template for new progeny minus-sense nucleocapsids.

The virally encoded RNA polymerase is bound to the nucleocapsid as a complex of P and L proteins. Neither of these proteins bind to isolated viral RNA, indicating that protein–protein interactions are necessary in order for binding to occur. Thus, the infecting virion delivers an RNA–protein complex into the cell that is capable of transcribing and replicating the viral RNA genome. Purified virions can transcribe the viral RNA genome into multiple subgenomic capped and polyadenylated mRNAs if disrupted with a mild detergent and incubated in a simple salt mixture containing RNA precursors. However, genome RNA replication does not occur unless these in vitro systems are supplemented with cell extracts that are capable of supporting ongoing protein synthesis. These observations illustrate the fact that there are fundamental differences between the two processes of RNA synthesis that must occur during the growth of respiroviruses (transcription and genome RNA replication). One process, genome RNA replication, requires concurrent protein synthesis and perhaps multiple host-cell factors, while the other, transcription, occurs independently from host factors other than energy sources and nucleotide supply. Both processes are described in more detail below.

The first step in the viral growth process, termed primary transcription to denote transcription directly from the infecting nucleocapsid template, initiates at the exact 3′ end of the genome in a primer-independent manner, first transcribing the short (approximately 50 nt) uncapped leader RNA. The synthesis of the leader RNA is followed sequentially by each of the other viral mRNAs in the order NP-P/V/C–M–F–HN–L. There is a polarity to the transcription process, so that genes located at the 3′ end of the viral genome are transcribed more frequently than those at the 5′ end. Each of the mRNAs is transcribed and present in infected cells as a function of its relative location on the negative sense viral genome. This polarity of transcription is a property of the viral coded RNA-dependent RNA polymerase complex.

The NP transcript is most abundant in infected cells and the L protein transcript is least abundant. The polymerase appears to pause at each intergenic junction and either reinitiates transcription at the next gene downstream or, alternatively, detaches from the nucleocapsid template and reinitiates upstream at the 3′ leader region that contains the polymerase binding site or promoter. This 'decision' made by the polymerase at each gene junction, together with the fact that there is a single polymerase entry site at the 3′ end of the genome, explains the sequential and polar nature of transcription. Transcription of each gene depends upon successful transcription and termination of the preceding upstream gene. Each mRNA is capped and methylated at its 5′ end and polyadenylated at its 3′ end, all carried out by the viral polymerase complex. Polyadenylation of the transcripts occurs through a polymerase chattering mechanism at a conserved stretch of U residues (U_5) at the end of each gene. The transcription of the *P* gene is more complex, and is discussed in more detail below.

THE 'RULE OF SIX'

The genomes of respiroviruses contain a total number of nucleotides that are evenly divisible by six. Taking advantage of the ability to generate recombinant infectious viruses from DNA clones ('reverse genetics'), it was observed that recombinant Sendai virus genomes that have a nucleotide number not divisible by six were

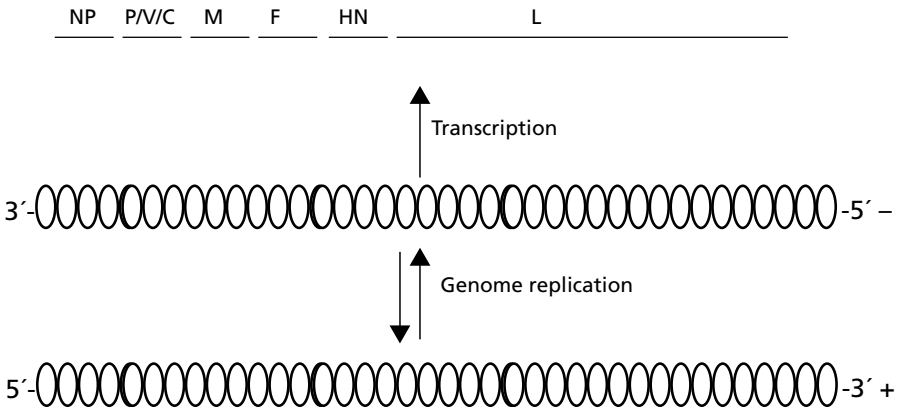

Figure 7 *Transcription and genome RNA replication of respiroviruses*

still assembled efficiently into nucleocapsids, but these genomes were very inefficiently transcribed or replicated (Pelet et al. 1996). This requirement for an optimal nucleotide number, or length evenly divisible by six, is referred to as the 'rule of six.' According to this model, the phasing of the nucleocapsid protein subunit on the viral genome is such that each protein subunit interacts with six nucleotides, and this phasing is important to maintain proper alignment of the 3′ *cis*-nucleotide sequences that are recognized by the viral RNA polymerase complex during transcription and replication. Experimental evidence for this model has been obtained (Pelet et al. 1996; Kolakofsky et al. 1998; Vulliemoz and Roux 2001), and suggests that there is an optimal spacing for promoters on the viral genome relative to the NP proteins.

POLYCISTRONIC mRNAS AND ALTERNATE READING FRAMES

For five of the six genes, transcription generally leads to generation of a single mRNA species that encodes a single protein molecule. However, the *P* gene of respiroviruses encodes a number of proteins and, in several members of the family, more than one mRNA is synthesized. Each of the *P* genes of all of the members of this virus genus is transcribed directly into an mRNA that encodes the P protein. This mRNA also encodes a number of smaller protein products in an alternate reading frame from the P protein, and hence the P mRNA is bi-cistronic. The largest open reading frame encodes the P protein, of 568–603 amino acids in length. The second ORF, near the 5′ end of the mRNA, is translated into a number of proteins called C, C′, Y1, and Y2. These 'C' proteins, as they are commonly called, are a nested set of carboxy-coterminal proteins, with each protein encoded in the same reading frame, but differing by its start site on the mRNA. Not each member of the family encodes each protein. Sendai virus encodes all four, HPIV-1 encodes C′ and C, while HPIV-3 and BPIV-3 encode just the C protein (Giorgi et al. 1983; Curran and Kolakofsky 1988). In Sendai virus the C, Y1, and Y2 proteins are synthesized by ribosomal choice at separate AUG codons, while C′ is initiated using an ACG codon. All of these proteins are small (175–215 amino acids) and basic, with isoelectric points of over 10. The functions of the C proteins are incompletely understood. The C protein of HPIV-3 and the C proteins of Sendai virus are apparently required for virus growth in cultured cells since recombinant viruses that do not express these proteins replicate poorly (Kurotani et al. 1998; Latorre et al. 1998). In addition, as discussed below, these proteins may function in pathogenesis in the infected host.

NONTEMPLATED NUCLEOTIDE ADDITION

The *P* gene of most respiroviruses, in addition to encoding the P and 'C' proteins, also encodes at least one other protein using a second mRNA transcribed from the gene (HPIV-1 is the exception). The process by which this second mRNA is produced has been referred to as RNA editing, or nontemplated nucleotide addition. A sequence of nucleotides in the *P* gene is recognized by the viral polymerase as a signal for 'stuttering,' and the polymerase either ignores this stuttering signal and transcribes the P mRNA, or stutters and incorporates one or two nontemplated G residues at the precise editing site on the mRNA (Thomas et al. 1988; Vidal et al. 1990a, b; Hausmann et al. 1999a, b). The consequence of this nontemplated nucleotide addition is that the resultant mRNA allows access to a conserved short open reading frame called V. The V protein contains the N-terminus of the P protein fused to the V ORF. This V ORF is highly conserved among the viruses, is cysteine-rich and has been shown to bind zinc (Paterson et al. 1995). It is dispensable for viral growth in cell culture, and appears to function as a pathogenesis factor (see Interaction with the host cell). In several respiroviruses, addition of two nontemplated G residues allows access to a second ORF termed D (Galinski et al. 1992). Thus the *P* gene of most respiroviruses encodes a number of protein products through alternate codon usage and RNA editing.

THE SWITCH FROM TRANSCRIPTION TO REPLICATION

Replication of the viral genomic RNA is a process both linked to and distinct from transcription of the genomic RNA. Unlike transcription, replication of the viral RNA genome depends on ongoing protein synthesis, and therefore is linked to prior transcription of the viral genome. In addition, during the process of genome RNA replication, the nascent RNA molecule is assembled into the characteristic helical nucleocapsid structure. During replication all signals to the viral polymerase are ignored, including the transcriptional termination signals at the ends of each gene and the capping, methylation, polyadenylation, and RNA editing signals that are present on the template RNA. The viral genome and antigenome contain 3′U-OH and 5′ pppA, respectively, rather than a cap and a poly(A) tail as in the mRNAs encoded by the genome.

Both transcription and genome RNA replication require the nucleocapsid template and the L and P proteins. The requirement for ongoing protein synthesis in order for RNA replication to occur is in part a consequence of the fact that the newly synthesized replication molecules are coassembled into nucleocapsids, and therefore NP protein is required in stoichiometric levels corresponding to the viral genome and antigenome RNAs (approximately 2 500 NP molecules per genome RNA). The NP protein that serves as the substrate for this assembly (NPo) is complexed with the P protein (Horikami et al. 1992). Binding of the P protein to free NPo is thought to prevent the self-assembly of free NP

protein into higher order structures, and thus P protein acts as a molecular chaperone, delivering the NP to the assembling nucleocapsid while not, itself, becoming a part of the structure. The second stage of genome RNA replication occurs when the newly replicated and encapsidated full-length plus-stranded RNA (antigenome)-containing nucleocapsids are copied into negative-strand RNA-containing progeny nucleocapsids identical to the nucleocapsid that is packaged into progeny viral particles. These progeny viral nucleocapsids are templates for transcription and can greatly amplify the amount of viral mRNA and protein produced in an infected cell.

THE *NP* GENE

The nucleocapsid protein NP of respiroviruses is encoded by the 3′-proximal gene and is the most abundant viral protein in the infected cell. The protein in Sendai virus is 524 amino acids in length and is phosphorylated at its C-terminus (Hsu and Kingsbury 1982; Ryan et al. 1993). The protein's main function is to coassemble with genomic and antigenomic RNAs to form the template for transcription and replication, the genome- and antigenome-containing nucleocapsid. When NP is expressed in the absence of other viral proteins it self-assembles into structures resembling viral nucleocapsids, suggesting that it can form higher order assemblies through protein–protein interactions. In infected cells, NPo is complexed with the P protein. Interaction with P protein prevents aggregation of free NPo, and it is the NPo–P protein complex that serves as the substrate for assembling NP/RNA nucleocapsid complexes. In addition to NP–NP and NPo–P interactions in nucleocapsid assembly, the NP protein on the nucleocapsid binds to the viral RNA and to the P subunit of the RNA polymerase of the virus. It has been demonstrated that the N-terminal 400 amino acids of the NP protein of Sendai virus are required for assembly into nucleocapsid templates (Buchholz et al. 1993; Curran et al. 1993). Further, these same 400 N-terminal amino acids of NP also retained the NPo–P interacting activity (Homann et al. 1991; Buchholz et al. 1994; Myers and Moyer 1997; Myers et al. 1997; Myers et al. 1999). The C-terminal portion of the protein appears to be necessary for binding of the P protein to the nucleocapsid (Ryan et al. 1993; Buchholz et al. 1994).

THE *L* GENE

The L proteins of all respiroviruses are greater than 2 000 amino acids in length and are encoded by approximately half of the viral genome. L is the least abundant protein in virus particles and in infected cells. It is likely that all of the enzymatic activities required for mRNA synthesis and genome RNA replication (polymerization, capping, methylation, polyadenylation) are encoded within this large multifunctional protein. However, a detailed understanding of the structure/function of the L protein has yet to be obtained.

Sequence alignments have identified six conserved domains in the protein, (I–VI) (Poch et al. 1990; Sidhu et al. 1993). Several of the domains contain conserved sequence motifs that suggest possible functions. Domain II has a conserved charged RNA binding motif found in several other viruses (Smallwood et al. 1999). Domain III has a motif found in several other virus L proteins that has phosphodiester bond-forming activity (Smallwood et al. 2002). Domain VI contains a potential nucleotide binding motif. Domain III contains a motif found in the active site of several positive-stranded RNA virus polymerases and is believed to contain the polymerase active site (Jin and Elliott 1992; Sleat and Banerjee 1993; Schnell and Conzelmann 1995). Domains IV and V have no homology with any known polymerase-associated motifs.

The L protein, in order to be functional, must complex with the P protein and via this interaction bind to the nucleocapsid template. The P protein binding site has been localized to the N-terminal 350 amino acids of the L protein of Sendai virus (Holmes and Moyer 2002). A similar picture is emerging for the L protein of HPIV-3, where a short stretch of amino acids at the very N-terminus of the L protein interacts with the P protein of the virus (Malur et al. 2002). The L protein itself is an oligomer, and the oligomerization domain has been mapped to the N-terminal 174 amino acids (Cevik et al. 2003). However, L protein expressed alone is rapidly degraded, and its stability is increased by coexpression of the P protein (Horikami et al. 1997). It has been proposed that the L protein first oligomerizes, and then these oligomeric complexes interact with a complex of the P protein forming a stable and active RNA transcriptase/replicase complex (Cevik et al. 2003). The stoichiometry of the proteins in this polymerase complex have been suggested to be either L2–P4 or L2–P8. What is certain (see below) is that the P protein is a tetramer, while the state of the L protein is less certain at this time.

THE *P* GENE

The *P* gene of respiroviruses encodes a number of protein products, as described above. The P protein is the only one of these proteins that is essential for RNA synthesis. P is a phosphoprotein that acts as a molecular chaperone for the NPo protein in nucleocapsid assembly. However, the role that phosphorylation plays in modulating the function of the protein, if any, is uncertain (Hu et al. 1992, 1999). P is also an essential component of the viral RNA polymerase, forming a complex with the L protein both in solution and on the template, as well as serving to mediate binding of the polymerase complex to the nucleocapsid via P–NP interactions. Several facts have emerged concerning the

structure/function of the P protein. Firstly, it oligomerizes into a tetramer. A partially resolved molecular structure suggests the P protein complexes with itself via coiled-coil motifs (Tarboubiech et al. 2000a, b). Second, it complexes with the L protein to form the polymerase complex (Curran et al. 1994; Smallwood et al. 1994; De et al. 2000; Bousse et al. 2001). Third, it mediates binding of the polymerase to the nucleocapsid template; L does not bind to the nucleocapsid template alone (Horikami and Moyer 1995). Last, P acts as a molecular chaperone for NP during nucleocapsid assembly and prevents NP from self-assembling into higher order structures (Curran et al. 1995b; Horikami et al. 1996).

Several of the domains on the P protein that participate in these varied activities have been mapped. The C terminus of the protein is capable of replacing the intact protein in supporting transcriptional activities (Curran et al. 1994). This fragment contains the domains/motifs required for oligomerization of the protein, for its interaction with and stabilization of the L protein complex, and for its ability to bind to the nucleocapsid template (Ryan and Portner 1990; Curran et al. 1994, 1995a; Smallwood et al. 1994; Bowman et al. 1999; De et al. 2000; Bousse et al. 2001). The only domain or motif so far mapped to the N-terminus is that required for its chaperone function(Curran et al. 1995b).

Assembly and budding

Respiroviruses are formed by budding of newly replicated and assembled nucleocapsids containing the viral RNA genome along with the P and L proteins through modified areas of the plasma membrane that contain the F and HN transmembrane glycoproteins and the M protein. In polarized epithelial cells, the viruses bud from the apical surface of the cell. A detailed understanding of the final assembly and budding process is lacking. However, it is likely that the nonglycosylated M protein binds to the nucleocapsid, condensing it, and preventing it from being transcribed or replicated. The M protein also likely interacts with the cytoplasmic tails of the HN and F proteins, and thereby mediates the alignment of the nucleocapsid and the areas of the plasma membrane containing viral glycoproteins in preparation for budding (Mottet et al. 1996, 1999; Coronel et al. 1999, 2001; Ali and Nayak 2000; Takimoto et al. 2001).

The M proteins of respiroviruses are small basic proteins and are a major component of virions. Their role in budding has been clearly shown by demonstrating the formation of virus-like particles in cells expressing just the M protein of HPIV-1 (Coronel et al. 1999, 2001). Interestingly, when NP was coexpressed, the budded particles contained structures closely resembling helical viral nucleocapsids. In similar systems, expression of the F protein alone led to the formation of virus-like particles (Takimoto et al. 2001). These data indicate that there are inherent properties of more than one respirovirus protein that can lead to the formation of virus particles during the budding process, and there is specificity in protein–protein recognition during this budding process.

Interaction with the host cell

EVASION OF HOST DEFENSE MECHANISMS

Host cells have developed a variety of countermeasures in the face of viral infection. In some of these, an intracellular environment is created that is less hospitable for virus replication (the interferon (IFN)-induced antiviral state). Some cell types undergo apoptosis, which limits viral replication. Many viruses have been found to posess strategies for evading these host immune responses, particularly the innate immune response that plays a key role in controlling virus infection. Many viruses encode gene products that are capable of inhibiting the host interferon response (Katze et al. 2002). For the paramyxoviruses, evasion of this response has been found to be mediated by the C and V proteins.

The Sendai virus *C* gene was one of the earliest examples of an overlapping gene (Giorgi et al. 1983). The *C* gene open reading frame is found overlapping the amino-terminal end of the open reading frame for the P and V proteins (which are also expressed from the *P* gene mRNA via the mechanism of mRNA editing (Giorgi et al. 1983; Bellini et al. 1985), discussed in detail in Primary transcription and replication). C proteins carry a net positive charge and are expressed from the second ORF (+1 with respect to P). For Sendai virus, evasion of the interferon system is accomplished in several ways by the C protein (Garcin et al. 2003). Sendai virus C protein binds STAT1, preventing its activation in response to IFN, and the carboxyl part of the C protein mediates this activity. A phenylalanine at position 170 of C is also critical for blocking STAT1 activation (Gotoh et al. 2001; Takeuchi et al. 2001; Garcin et al. 2002). In addition, Sendai C protein targets STAT1 for degradation, and the amino-terminal residues of the C proteins mediate this activity (Garcin et al. 2003).

The V proteins require the pseudotemplated addition of a single G residue to switch from the N terminal P to C terminal V ORF. V proteins of the parainfluenza viruses are fusion proteins containing a negatively charged and phosphorylated N terminus and a short, cysteine-rich zinc-binding domain at their C terminus (Paterson et al. 1995; Lamb and Kolakofsky 2001). The V proteins are involved in a wide range of mechanisms for evading the immune response. These have been found thus far to include prevention of apoptosis (He et al. 2002; Wansley and Parks 2002), cell-cycle alterations (Lin and Lamb 2000), inhibition of double-

stranded RNA signaling (He et al. 2002; Poole et al. 2002), and prevention of IFN biosynthesis (He et al. 2002; Poole et al. 2002; Wansley and Parks 2002). V protein expression has been shown for several paramyxoviruses to inhibit IFN-responsive STAT proteins. The strategies whereby different V proteins inhibit STAT proteins have been found to be highly diverse. Most information about the function of these V proteins have been derived from study of closely related paramyxoviruses. For example, SV5 V proteins target STAT1 for degradation (Didcock et al. 1999; He et al. 2002), while HPIV type 2 V protein targets STAT2 (Parisien et al. 2001; Andrejeva et al. 2002). Mumps virus V protein can target both STAT1 (Nishio et al. 2002) and STAT3 (Ulane et al. 2003) and can also interact with cellular RACK1, potentially modifying IFN receptor activity (Kubota et al. 2002). Nipah virus V protein sequesters STAT1 and STAT2 in high-molecular-weight cytoplasmic complexes, thus preventing STAT protein nuclear accumulation (Rodriguez et al. 2002).

USE OF CELLULAR MACHINERY FOR VIRAL ENTRY AND/OR ASSEMBLY

After entering the target cell via fusion with the cell membrane, and release of the viral molecules into the cytoplasm, respiroviruses carry out their replicative cycle within the cytoplasm (as discussed in Primary transcription and replication) and then assemble and bud at the cell surface (discussed in Assembly and budding). The potential role of cytoskeletal molecules in the process of viral entry (Pastey et al. 1999, 2000), as well as the fascinating question of how the various viral constituents are directed during the parasitic phase of the life cycle to the correct cellular locations, remain to be clarified. It is possible that entry, fusion, and/or budding involve the participation of the cellular actin cytoskeleton, as well as microtubule function (Tashiro et al. 1993; Gupta et al. 1998; De and Banerjee 1999; Bose et al. 2001). In addition, host cellular proteins that are involved in cell mobility could be involved. For the related virus respiratory syncytial virus (RSV), it was shown that F binds RhoA, a small GTPase of the Ras superfamily, in yeast two-hybrid interaction studies (Pastey et al. 1999). RhoA controls cellular functions including actin reorganization, cell morphology, and motility. The interaction with RSV F was shown in vivo by mammalian two-hybrid assay and in RSV-infected HEp-2 cells by coimmunoprecipitation. Cells that overexpressed RhoA were used to show that RhoA correlated with fusogenicity by RSV, suggesting RhoA could play a role in RSV-induced syncytium formation. Subsequently, RhoA peptides were used to show that cell–cell fusion by HPIV-3 could be inhibited by a RhoA peptide corresponding to the region that binds RSV F (Pastey et al. 2000), suggesting a common component of the entry/fusion mechanisms involving interaction between the F proteins and RhoA.

CLINICAL AND PATHOLOGICAL ASPECTS OF INFECTION WITH HUMAN PARAINFLUENZA VIRUSES

Croup (laryngotracheobronchitis)

ETIOLOGY

The parainfluenza viruses types 1, 2, and 3, taken together, are the most important cause of croup. HPIV-3 alone is responsible for approximately 11 percent of pediatric respiratory hospitalizations (Murphy 1988; Chanock 1990) and is a predominant cause of croup in young infants. HPIV 1 and 2 tend to infect older children and adolescents. Infection with HPIV in immunocompromised children (for example, transplant recipients) has been associated with a wide range of disease, from mild upper respiratory symptoms to severe disease requiring mechanical ventilation and leading to death, especially in young children, those whose infections occur soon after transplant, and those with the most intensive immunosuppression (Apalsch et al. 1995).

Other viral causes of croup include adenovirus, influenza A and B, rhinoviruses, RSV, measles and enteroviruses. Bacterial causes (such as *H. influenzae*, Group A hemolytic strep, *C. diphtheriae*, *S. pneumoniae*, *S. aureus* and *Mycoplasma pneumoniae*) are much less frequent. While RSV is the leading cause of acute lower respiratory tract infection in young children and causes a significant percentage of croup, it is more commonly seen as a cause of bronchiolitis. Influenza viruses (A and B) are also important causes of serious lower respiratory tract disease in children. Influenza A is an important cause of croup, as well as pneumonia and pharyngitis-bronchitis. Diphtheria caused by *Corynebacterium diphtheriae* is now a rare cause of croup. However, this organism may infect the larynx, trachea, and bronchi by extension from a pharyngeal infection or by primary infection, and result in a croupy cough with stridor.

EPIDEMIOLOGY

HPIV1 causes large seasonal outbreaks of illness, with rises in the number of croup cases every other year (odd-numbered years). HPIV-2 outbreaks generally follow those caused by HPIV-1. HPIV-3, in contrast, causes outbreaks each year, generally in the spring or summer (Hall 2001).

PATHOGENESIS IN THE HUMAN

Parainfluenza viruses replicate in the epithelium of the upper respiratory tract, and spread to the lower respiratory tract within 3 days. The pathogenesis in the lung

has not yet been well studied as it has for RSV. Epithelial cells of the small airways become infected with resultant necrosis and imflammatory infiltrates. The interplay between virus-induced cell damage, beneficial immune responses and inflammatory responses that contribute to disease for HPIV-3 is still unknown, and this is an area of active investigation for parainfluenza virus research.

CLINICAL MANIFESTATIONS

Croup is the most common clinical manifestation of HPIV infection. Inflammatory obstruction of the airway produces the clinical picture in all forms of infectious croup, which include acute laryngitis, laryngotracheitis, and laryngotracheobronchitis. A mild upper respiratory syndrome usually precedes the clinical manifestations of croup. The clinical findings are produced by inflammatory obstruction of the airway in all forms of the illness. The severity and extent of the infectious process (and, likely, of the inflammatory response) determine the sites of obstruction in the laryngotracheobronchial tree. Milder cases are characterized by hoarseness and a barking ('croupy') cough. Low-grade fever, loss of appetite, and malaise may be the only constitutional signs, respiratory distress is absent or minimal, and the condition responds promptly to appropriate treatment and subsides in a few days. In patients with severe acute laryngitis the infection may descend rapidly to the trachea and bronchi, causing increased respiratory distress evidenced by nasal flaring and inspiratory retractions. In these cases, the site of obstruction is usually the subglottic area. Hoarseness is more marked, and breathing may become rapid and labored, with inspiratory stridor and retraction of the suprasternal notch, the supraclavicular spaces, the substernal region, and the intercostal spaces. Expiratory wheezes and various types of bronchitic rales are heard on auscultation of the chest. The illness can rapidly progress to respiratory failure with hypoxia, weakness, decreased air exchange, and death. Agitation, crying, and manipulation of the airway can aggravate the respiratory distress. The white blood cell count is frequently normal or mildly elevated, and radiographs classically show a 'steeple sign' indicative of subglottic edema.

In patients with infection limited to the laryngeal area, chest auscultation reveals inspiratory stridor and impaired aeration. The main site of obstruction lies below the vocal cords, where subglottic tissues bulge to meet in the midline. An exudate may add to the airway obstruction. In laryngotracheobronchitis, the most extensive type of croup, expiratory wheezes rales are heard on auscultation of the chest. Atelectasis resulting from plugging of a bronchus with exudate may result in localized areas of absent breath sounds, bronchial breathing, and dullness to percussion. If a main bronchus becomes plugged, cyanosis worsens, and the heart and mediastinum may be shifted to the affected side.

DIAGNOSIS

Diagnosis of HPIV infection in the clinical setting can be made by viral isolation, or by detection of antigen or nucleic acid. All three types of methods are currently available, and the use of reverse transcription polymerase chain reaction (RT-PCR) allows for the diagnosis of several respiratory viruses simultaneously. A multiplex RT-PCR assay for detecting HPIV 1, 2, and 3 was developed in 1995 (Fan and Henrickson 1996) and there is currently a highly sensitive and specific multiplex assay for detecting these viruses along with RSV and influenza viruses (Fan and Henrickson 1996; Fan et al. 1998; Kehl et al. 2001). These assay kits, as well as kits for antigen detection, allow for screening of children and are likely to be used more commonly in the future as more therapies for pediatric respiratory viruses become available.

TREATMENT

Novel antivirals for HPIV are under investigation, including molecules designed to inhibit viral fusion and entry, but no specific therapy is available as of November 2003. Most children with croup do not require hospitalization, and treatment is supportive, aimed at maintaining the airway and hydration. Avoiding agitation of the child is important, in order not to compromise the airway. If necessary, humidified supplemental oxygen may be administered by hood, mask, or nasal cannula. Steroids are beneficial in the treatment of croup (Kairys et al. 1989; Orlicek 1998; Wright et al. 2002) and nebulized steroids can be effective (Husby et al. 1993; Klassen et al. 1994, 1998; Johnson et al. 1998). Racemic epinephrine or L-epineprhine has been successfully used for the treatment of more severe cases of croup (Kuusela and Vesikari 1988; Waisman et al. 1992).

PREVENTION

The development of a vaccine for the parainfluenza viruses has been hampered by the need to induce an immune response in young infants whose immature immune systems and whose maternal antibody both interfere with the development of an adequate immune response. Experimental vaccines are under evaluation, with reasonable expectation that a vaccine for HPIV-3, and perhaps also HPIV1, will soon be feasible. Several strategies have been recently evaluated for HPIV-3 vaccines. Bovine parainfluenza type 3, attenuated in humans by nature of host range, has been shown to be infectious in seronegative recipients, with most vaccinees shedding virus or developing an immune response (Clements et al. 1996; Karron et al. 1996). Cold-adapted mutants of parainfluenza have been evaluated in both chimpanzees and in healthy infants. A cold-passaged mutant (cp45) was evaluated in seronegative chimpanzees and found to be attenuated in the upper and lower

respiratory tracts. Immunized animals were resistant to wildtype PIV-3 challenge. The vaccine was also well tolerated when given intranasally to HPIV-3-seropositive and -seronegative children. One dose of vaccine induced a serum hemagglutination-inhibiting antibody response in 81 percent of vaccinees (Hall et al. 1993; Karron et al. 1995a, 1995b, 1995c). As for RSV, it is likely that with the recent increase in our understanding of the molecular contributions to attenuation, engineered live HPIV-3 vaccines can be designed to be ideally attenuated and immunogenic (Skiadopoulos et al. 1999a, b, c; Tao et al. 1999), and that this technology will enhance our ability to rapidly develop effective parainfluenza virus candidate vaccines suitable for children in the future.

Acute bronchiolitis

ETIOLOGY

While RSV is the leading cause of bronchiolitis in young children, accounting for 50–90 percent of all bronchiolitis hospitalizations, after RSV the human parainfluenza viruses type 3, and to a lesser extent type 1 and 2, are the most common causative agents of bronchiolitis (Collins et al. 1996).

PATHOGENESIS

Bronchiolitis is the result of a balance between cellular damage mediated by the viral pathogen and injury caused by the immune response of the host (Welliver 2000). Virus first replicates in the nasopharyngeal epithelium and spreads to the lower respiratory tract. Viral replication in the small airways causes inflammation, sloughing and necrosis of epithelium. Edema and increased mucous secretion cause plugging of the small airways, atelectasis, airway narrowing, and obstruction. Primary infection tends to be the most severe, and it is unclear whether this is due to immunopathologic mechanisms, immunologic immaturity or simply to the small size of the airways of the infected infants.

The immunology and immunopathogenesis of HPIV infection are complex and not fully understood, although it is clear that both humoral and cellular components of the immune system contribute to both pathogenesis and protection. Understanding of the interplay between virus-induced cell damage, beneficial immune responses and inflammatory responses will be key for the development of safe vaccine strategies and effective therapeutic interventions. This has been important, for example, in understanding mechanisms that may have contributed to enhanced disease observed after the administration of a formalin-inactivated RSV vaccine to infants (Scott et al. 1978; Connors et al. 1992; Waris et al. 1996; Prince et al. 1999, 2001; Openshaw et al. 2001). The pathologic changes that are present in children that have died with parainfluenza infection suggest exaggerated inflammation (Aherne et al. 1970; Downham et al. 1975).

HPIV primary infection does not confer permanent immunity, and in fact repeated reinfection within a year of the previous infection is common in young children. Although reinfection with HPIV-3 can occur, immunity is usually sufficient to restrict virus replication from the lower respiratory tract and prevent severe disease. Mucosal IgA levels correlate with protection from replication of parainfluenza viruses in humans (Smith et al. 1966; Tremonti et al. 1968). Cell-mediated immunity is also an important contributor to prevention of disease: HPIV-3 infection of T cell-deficient infants can result in fatal giant-cell pneumonia (Smith et al. 1966; Tremonti et al. 1968) and HPF-induced pneumonia has a 30 percent mortality in bone marrow transplant recipients (Wendt et al. 1992). The desirablilty of a vaccine that would protect against HPIV-1, -2, and -3 is clear. An inactivated HPIV-1, -2, -3 vaccine used in infants in the late 1960s was immunogenic, but did not offer protection from infection (Chin et al. 1969; Fulginiti et al. 1969), and live attenuated viruses are now being considered as vaccine candidates (Clements et al. 1991; Karron et al. 1995a, 1995b). This underscores the importance of better defining the virus–host interactions that result in pathology versus immunity. The cotton rat (*Sigmodon hispidus*) is an excellent model for HPIV lower respiratory infection (Porter et al. 1991) and for testing potential therapies (Prince and Porter 1996), since experimental infection leads to bronchiolitis and interstitial pneumonia, mimicking human disease. When cotton rats were infected with wild-type HPIV-3 and with variant viruses containing single amino acid changes in the receptor-binding protein HN the pathology observed in lungs of infected animals was distinct: infection with viruses with variant HN resulted in far more severe alveolitis and interstitial pneumonitis even though there was little difference in magnitude and duration of virus replication (Prince et al. 2001). These findings are reminiscent of the cases of unexplained severe HPIV-3 disease in presumably normal children, and present a model to explore the role of HN–receptor interaction in immunopathogenesis that may translate into better understanding of HPIV-3 disease.

CLINICAL MANIFESTATIONS

Bronchiolitis usually begins as an ordinary upper respiratory tract infection with nasal discharge, cough, slight fever, fretfulness, and loss of appetite. The infant may rapidly worsen and develop rapid labored breathing, with retraction of the intercostal spaces, use of accessory respiratory muscles and cyanosis. Increasing obstruction leads to progressive hypoxemia, followed by exhaustion and death. Respirations are rapid, shallow, difficult, and often wheezy, with a rate of 60 to over 80 per minute. Inspiratory retraction is seen in the

suprasternal notch and the intercostal and subcostal spaces. Cyanosis appears or is intensified during coughing or crying and can be continuous if the obstruction is severe.

Physical findings include overinflated lungs with hyperresonance to percussion. The diaphragm is depressed, and expiration is prolonged, and wheezing is prominent. Initial hypoxemia may be followed by respiratory acidosis and hypercapnia. Hyperinflation and diffuse interstitial pneumonitis are seen on chest X-ray in severe disease.

Risk factors predisposing to serious disease include underlying medical conditions such as prematurity, cardiopulmonary disease, immunodeficiency, metabolic disease, and some neuromuscular disorders. Assessment of the risk for progression to severe disease includes evaluation of underlying medical conditions, and the overall clinical status of the child. An oxygen saturation less than 95 percent by pulse oxymetry is a reliable objective predictor of progression to severe disease.

TREATMENT

The treatment of acute bronchiolitis should aim to relieve bronchiolar obstruction, correct hypoxemia and acidosis, control potential cardiac complications, provide supportive measures, and prevent or treat secondary bacterial infection.

Management of bronchiolitis is mainly supportive and symptomatic, aimed at providing adequate oxygenation and hydration. Close monitoring of the respiratory status is essential and cardiovascular support may be required in the presence of manifestations of developing heart failure. If the child has very severe bronchiolitis that progresses in spite of these measures, assisted ventilation may be needed.

The use of alpha- and beta-adrenergic agonists remains controversial. The individual response to these therapies is variable and their use must be assessed in each individual case. A trial of inhaled bronchodilators and evaluation of the response is recommended in most cases, particularly in patients with past history of reactive airway disease or asthma. If there is no significant improvement, the therapy may be discontinued.

Cellular damage caused by the immune system of the host is an important component in viral bronchiolitis. Because of this element of inflammation, corticosteroids have been considered and studied for the treatment of bronchiolitis, but to date these studies have failed to demonstrate significant efficacy. Other antiinflammatory agents, such as cromolyn sodium, budesonide, antileukotrienes, and antikinins, are currently being evaluated.

Pneumonia

ETIOLOGY

A variety of pathogens are etiologic agents of pneumonia in children in addition to the human parainfluenza viruses, including RSV and influenza virus and numerous bacterial agents. The incidence of viral pneumonia far outstrips that of bacterial and fungal pneumonia. The clinical manifestation of these various agents is dependent on the pathogen, the child's age and the immune status.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical diagnosis of pneumonia is supported by the findings of fever, tachypnea, and crackles on lung examination. For many patients, this evaluation is sufficient and the need for pursuing further diagnostic evaluation, including complete blood count, chest radiograph, and blood culture, is based on the degree of toxicity and illness of the child. The most reliable indicator of a positive chest radiograph is the clinical finding of tachypnea. Approximately two out of three of patients with pneumonia present with this finding.

Clinical evidence may not be sufficient to differentiate between viral and bacterial etiologies. Conjunctivitis and otitis media are more often associated with bacterial than viral pneumonia (Ramsey et al. 1986), and wheezing is more commonly associated with viral etiologies (Turner et al. 1987; Forgie et al. 1991). The chest radiograph does not differentiate bacterial from viral pneumonia when radiographs are compared in a blinded fashion (McCarthy et al. 1981; Courtoy et al. 1989). Elevated CRP and absolute neutrophil are more reliable indicators of bacterial pneumonia than clinical and radiologic evidence (Korppi et al. 1997; McIntosh 2002).

With the isolation of respiratory syncytial virus (RSV) in 1956, and its association with serious lower respiratory tract infection in young children, the significance of RSV as an important human pathogen was established. Recent discovery of human metapneumovirus (hMPV), a respiratory virus biologically and clinically related to RSV, has highlighted the importance of understanding the virus–host relationship between RSV and hMPV. The biology, replication, and virus and host factors that influence virus replication, immunity, and disease pathology are discussed.

HUMAN RESPIRATORY SYNCYTIAL VIRUS – THE TYPE SPECIES *PNEUMOVIRUS*

The *Paramyxoviridae* family includes numerous important human and avian respiratory tract pathogens. Human respiratory syncytial virus (HRSV) is a member of the *Pneumovirinae* subfamily and type species member of the *Pneumovirus* genus. RSV was first isolated in 1956 as the chimpanzee coryza agent (CCA) during an outbreak of respiratory illness in a chimpanzee colony (Morris et al. 1956). Shortly thereafter, RSV was isolated from an infant with bronchopneumonia, and from another infant with bronchitis (Chanock and Finberg 1957). It was named respiratory syncytial virus because of its characteristic ability to induce syncytia in cell lines. RSV is now recognized as a ubiquitous virus, and the most important cause of serious lower respiratory tract illness in infants and young children worldwide, as well as an important pathogen in the elderly, and those with compromised cardiac, pulmonary, or immune systems (Fixler 1996; Couch et al. 1997; Falsey 1998; Hall 1999; Simoes 1999; Falsey and Walsh 2000; Billings et al. 2001; CDC 2002; Staat 2002). RSV, followed by the parainfluenza viruses, is the primary cause of hospitalization for respiratory tract illness in young children. The infection rate in young children approaches 70 percent in the first year of life (Glezen and Denny 1973), and in the USA, lower respiratory tract disease develops in 20–30 percent of

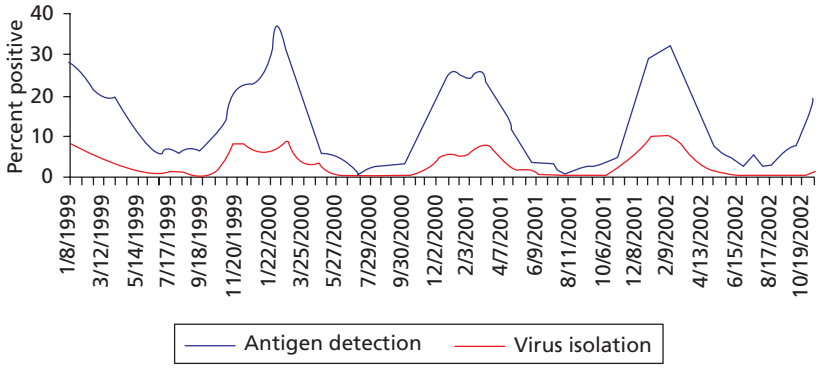

Figure 1 *The percent positive RSV tests in the USA from 1999 to 2002 by week of report to the National Respiratory and Enteric Virus Surveillance System. Weekly laboratory test result data are collected on a voluntary basis from reference laboratories in the USA. In the USA, RSV community outbreaks typically occur during late fall, winter, and early spring. There may be variation in the timing of outbreaks between regions and between communities in the same region.*

infected children requiring hospitalization (Shay et al. 1999). In immune compromised patients, or bone marrow or lung transplant recipients, RSV may cause respiratory failure leading to mortality rates of 70–100 percent (Hertz et al. 1989). RSV is a seasonal virus with peak rates of infection occurring annually during cold seasons in temperate climates, and in the rainy season in tropical climates. In the USA, most RSV infections occur during a period from October through March with peak activity usually in January or February (Figure 1). There are two major groups of RSV strains, A and B, and both strains circulate concurrently. The clinical severity of RSV infection has not been conclusively linked with infection by A or B strain. The significant public health burden mediated by RSV infection is exemplified by the dramatic infection rate in younger children, the percent of children hospitalized because of RSV-associated lower respiratory tract disease, and by the substantial mortality in the young and immune compromised. Despite four decades of efforts to unravel the complexities of RSV–host interactions, there is no effective vaccine to control RSV infection, and only limited prophylactic or therapeutic treatments. Although this work has led to a greater understanding of RSV immunobiology, significant efforts are still needed to understand the mechanisms of immunity and disease pathogenesis associated with infection, and their relationship to the newly discovered hMPV, in order to develop effective vaccines and treatments.

AVIAN PNEUMOVIRUS (APV) – THE TYPE SPECIES *METAPNEUMOVIRUS*

APV is a member of the *Pneumovirinae* subfamily, and type species member of the *Metapneumovirus* genus. In the USA, APV was first isolated in 1997 from turkeys with clinical signs of respiratory disease (Senne et al. 1997; Njenga et al. 2002). It is a ubiquitous virus that has been isolated from fowl in Africa, Europe, and North America and South America (Njenga et al. 2002). The clinical signs of infection in turkeys include conjunctivitis, rhinitis, sinusitis, and tracheitis, which led to it initially being named *Turkey rhinotracheitis virus* (Collins and Gough 1988; Jirjis et al. 2002a). APV causes upper respiratory infection in both turkeys and chickens, and may rapidly spread through flocks via respiratory aspirate (Alkhalaf et al. 2002). Infection by APV infection is generally not associated with mortality, but is associated with high morbidity and exacerbated secondary infections, although it is possible to have infection without clinical signs (Seal 2000; Alkhalaf et al. 2002; Chary et al. 2002). Recovery usually takes place within 10–12 days. Morbidity may be 100 percent, and mortality, usually due to secondary bacterial infections, ranges from 0 to 90 percent (Alkhalaf et al. 2002; Jirjis et al. 2002a; Njenga et al. 2002). All ages of fowl are susceptible; however, APV disease is more severe in young birds. There are two strains of APV recognized, A and B, based on differences in the *G* glycoprotein of the virus (Njenga et al. 2002). Nucleotide sequence analysis of the *G* glycoprotein gene has indicated that isolates from the UK and France are similar and belong to strain A, and isolates from Spain, Italy, and Hungary are identical, and belong to strain B (Njenga et al. 2002).

CLASSIFICATION

RSV is a nonsegmented negative-strand RNA virus belonging to the family *Paramyxoviridae* (order *Mononegavirales*) which consists of two subfamilies and five genera. *Morbillivirus*, represented by *Measles virus*, *Rubulavirus*, represented by *Mumps virus* that includes parainfluenza virus 2 (PIV2), parainfluenza virus 4, *Newcastle disease virus* (NDV), and *Simian virus 5* (SV-5), *Respirovirus*, represented by *Sendai virus* that includes parainfluenza virus 1 and parainfluenza virus 3 form the subfamily *Paramyxovirinae* (Figure 2). The

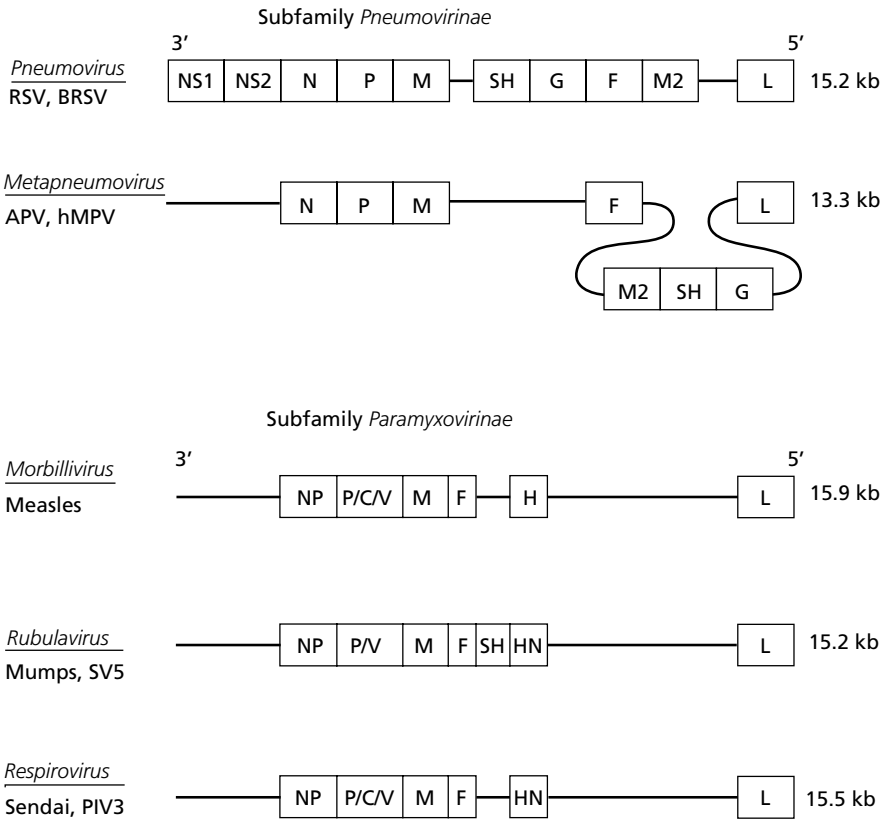

Figure 2 *Comparison of gene maps of members belonging to the* Pneumovirinae *and* Paramyxovirinae *subfamilies of nonsegmented negative-strand RNA viruses. The gene alignment is illustrated as genomic RNAs from 3′ to 5′. Each box represents a separate encoded mRNA, and the acronyms for the encoded proteins. The box sizes and spacing are not to scale. Protein names: NS, nonstructural protein; N/NP, nucleocapsid protein; P, phosphoprotein; M, matrix protein; M2, second matrix protein; SH, small hydrophobic protein, G/HN/H, attachment protein; F, fusion protein; L, large polymerase protein; C, nonstructural protein; V, cysteine-rich protein. The* Rubulavirus SH *gene is indicated for mumps virus and SV-5 members; however, NDV, PIV2, and simian virus 41 do not have an* SH *gene.*

Pneumovirus genus, represented by RSV, includes bovine, ovine, and caprine RSV, and the *Metapneumovirus* genus is represented by APV (or *Turkey rhinotracheitis virus*) and tentatively includes hMPV, forming the subfamily *Pneumovirinae* (Figure 2). The *Morbillivirus*, *Rubulavirus*, and *Respirovirus* genera are highly interrelated, sharing significant amino acid homology for many proteins; however, the *Pneumovirus* genus is substantially different. The pneumoviruses have fusogenic activity (Zimmer et al. 2001), but do not hemagglutinate or have hemolytic activity (Richman et al. 1971), and neuraminidase activity is absent in both *Morbillivirus* and *Pneumovirus*. Pneumoviruses also differ from other paramyxoviruses in the diameter of the helical nucleocapsid that is 12–15 nm, rather than 18 nm (Bhella et al. 2002). In addition, pneumoviruses encode a larger number of mRNAs, but the lengths of genomic RNAs are similar to paramyxoviruses (Figure 2).

Pneumovirus genome contains two nonstructural genes (*NS2*, *NS1*) followed by eight other genes namely, nucleocapsid (*N*), phosphoprotein (*P*), matrix (*M*), small hydrophobic (*SH*), surface attachment glycoprotein (*G*), surface fusion glycoprotein (*F*), second matrix (*M2*), and RNA-dependent RNA polymerase (*L*) in the order 3′-*NS1–NS2–N–P–M–SH–G–F–M2–L*-5′. By contrast, the *Metapneumovirus* genome lack *NS* genes, and has a different gene order given by 3′-*N–P–M–F–M2–SH–G–L*-5′.

PNEUMOVIRUS PROTEINS

Electron microscopy (EM) and negative staining have shown that pneumovirus virions are pleomorphic, consisting of a nucleocapsid surrounded by a lipid envelope with a diameter ranging from 150 to 300 mm (Joncas et al. 1969; Norrby et al. 1970; Bachi and Howe 1973). A thin section EM of RSV particles budding from the plasma membrane of HEp-2 cells is shown in Figure 3. The lipid bilayer that surrounds the nucleocapsid is derived from the host-cell plasma membrane during the budding process, and contains three virally encoded surface transmembrane glycoproteins: G, F, and SH. The virion matrix proteins, M1 and M2, are non-glycosylated, and the N, P, and L proteins associate with genomic RNA to form the nucleocapsid. The NS1

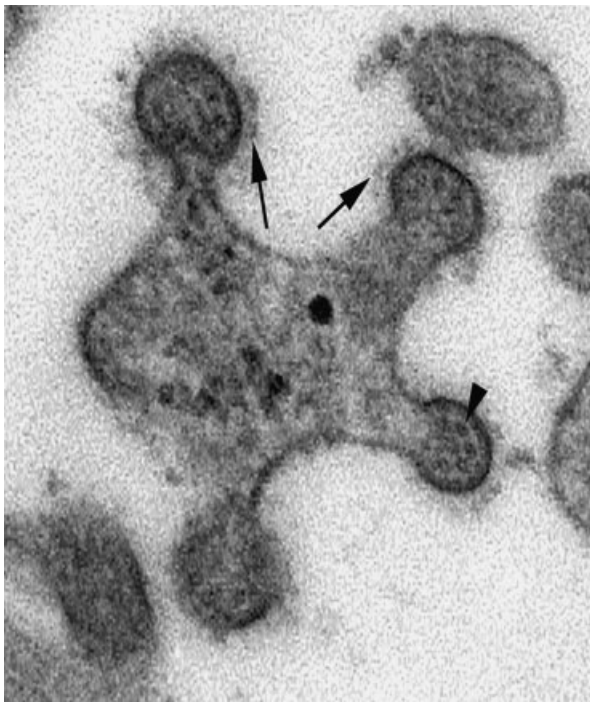

Figure 3 *RSV budding from the plasma membrane of HEp-2 cells. Cross-sections of the viral nucleocapsid (arrowhead) are enclosed within the viral envelope which has prominent surface projections (arrows). (Courtesy of C.S. Goldsmith, J. Hierholzer, and E.L. Palmer, Centers for Disease Control and Prevention, Atlanta, GA.)*

and NS2 proteins are not readily detectable in virions, but are found in RSV-infected cells.

The RSV genome consists of 15 222 nt that are transcribed into 11 major subgenomic mRNAs, each of which codes for a unique protein (Huang and Wertz 1982; Collins and Wertz 1983; Collins et al. 1984a, 1986; Dickens et al. 1984). The surface fusion glycoprotein (F), in combination with the surface attachment glycoprotein (G), is responsible for attachment, and the F glycoprotein is responsible for virus penetration and fusion of the viral envelope with host cell membranes and formation of syncytia. The F glycoprotein is structurally and functionally related to other paramyxoviruses (Collins et al. 1984b; Spriggs et al. 1986). It is a type I membrane glycoprotein of approximately 70 kDa that contains a cleaved N-terminal signal sequence anchored in the membrane by a C-terminal membrane anchor sequence allowing for >90 percent of the N-terminal molecule to be extracellular (Arumugham et al. 1989; Paradiso et al. 1989). The F glycoprotein is synthesized as precursor protein (F_0) in the endoplasmic reticulum consisting of a F_2 domain at amino acid positions 1–130, a cleavage site at amino acid positions 131–136, and an F_1 domain at amino acid positions 137–574. The F_0 protein precursor is cleaved by a trypsinlike protease into disulfide-linked F_1 and F_2 subunits in the trans-Golgi, constituting the biologically active form of the molecule. The F_2 domain is modified by the addition of N-linked sugars, and the F glycoprotein is expressed as a trimer or tetramer (Collins et al. 1984b; Johnson and Collins 1988).

The G glycoprotein has a number of genetic, structural, and functional differences that are unique among the *Paramyxoviridae* viruses, and most virus attachment proteins in general (Satake et al. 1985; Wertz et al. 1985, 1989). The G glycoprotein forms from a polypeptide precursor (32 kDa) that ranges in amino acid length (292–299 amino acids) depending on the virus strain (Martinez et al. 1999; Sullender et al. 1991). The precursor is co-translationally modified by the addition of high mannose N-linked sugars to form an intermediate of 45 kDa, that is followed by addition of *O*-linked sugars in the trans-Golgi to achieve a mature form of approximately 90 kDa (Wertz et al. 1989; Collins and Mottet 1992). Most of the carbohydrate is of the O-linked variety, thus the G glycoprotein has high serine, threonine, and proline content (Collins 1990; Collins and Mottet 1992). The high proline content may reduce highly folded secondary structure contributing to an extended structure. The G glycoprotein is also palmitylated (Collins and Mottet 1992). The G glycoprotein is a type II glycoprotein with a single N-terminal hydrophobic region (amino acids 38–66) that serves as a signal peptide and membrane anchor (Wertz et al. 1985; Vijaya et al. 1988; Roberts et al. 1994; Lichtenstein et al. 1996). Proximal to the membrane anchor region is an extracellular ectodomain. In the middle of the ectodomain is a short protein segment and four cysteine residues (173, 176, 182, and 186) that are highly conserved in all RSV isolates (Sullender et al. 1991; Teng and Collins 2002). This region contains a CX3C chemokine motif (amino acids 182–186) that may facilitate virus attachment to cells expressing the CX3C chemokine receptor, CX3CR1 (Tripp et al. 2001). Flanking this region are two glycosylation sites that are highly divergent among all RSV isolates (Cane et al. 1991; Sullender et al. 1991). The G glycoprotein is expressed both membrane-bound and secreted by initiation of translation at an alternate in-frame AUG codon located in the middle of the hydrophobic transmembrane region (Roberts et al. 1994). Approximately 15 percent of the G glycoprotein synthesized in infected cells is secreted in a soluble form lacking the cytoplasmic domain and part of the signal-anchor sequence, but retaining the same characteristics as the membrane bound form, e.g. glycosylation and antibody reactivity (Hendricks et al. 1987, 1988).

The SH protein is a short (64 amino acids) minor surface glycoprotein with unknown function. Unpublished results from our laboratory suggest that SH expression may regulate apoptosis by inducing expression of the anti-apoptosis gene, *IEX-1L* (Domachowske et al. 2000) in RSV-infected human epithelial cells. The SH protein is membrane-anchored at a centrally located anchor sequence such that only a third of the molecule

is extracellular. SH accumulates in the infected cell in different forms (Sho, SHg, SHp, SHt), but the SHo unglycosylated species is the most abundant form (Olmsted and Collins 1989; Collins et al. 1990a). All forms of SH, except for SHt, are transported to the cell surface, and only Sho and SHp are incorporated into the virion (Collins and Mottet 1993). The significance of the different forms is unknown, but conservation among human and bovine strains of RSV suggests that they may be involved in virus attachment, penetration, or viral uncoating (Collins et al. 1990a; Anderson et al. 1992), or may be important in regulating apoptosis.

RSV has three nucleocapsid-associated proteins, N, P, and L. The RNA binding protein, N, is a multifunctional protein of 391 amino acids that has a central role in transcription and replication of viral genomic RNA (Collins et al. 1984a, 1985). The phosphoprotein (P) is a key component of the viral RNA-dependent RNA polymerase complex, having two general functions as a transcription and replication factor, and as a chaperone for soluble L protein (Horikami et al. 1992). The P protein is smaller (241 amino acids) than most paramyxovirus P proteins (391–602 amino acids) and is dispensable for virus replication in vitro (Villanueva et al. 2000). However, phosphorylation of P protein is required for efficient virus replication in vitro and in vivo (Villanueva et al. 2000; Khattar et al. 2001). The large viral polymerase, L, is the least abundant of the structural proteins. The L protein is similar in length to other paramyxovirus counterparts (approximately 2 200 amino acids), but there is limited sequence homology within the paramyxoviruses (Stec et al. 1991). The N, P, and L proteins are the minimal *trans*-acting proteins required for RNA replication (Yu et al. 1995); however, RSV transcription and replication appears to lack the requirement that template length be an even multiple of an integer such as six, which is obligatory for nucleocapsid function of other paramyxoviruses, such as measles virus and Sendai virus (Samal and Collins 1996).

Unlike other negative-strand RNA viruses, pneumoviruses such as RSV have two matrix proteins, M and M2 (Collins et al. 1984a; Huang et al. 1985). The M protein is smaller (256 amino acids) than similar paramyxovirus counterparts (335–375 amino acids), and has limited sequence homology (Satake and Venkatesan 1984). The M2 protein (194 amino acids) is unique to pneumoviruses. M and M2 are nonglycosylated proteins that appear to be virion-associated. The M protein appears to functionally inactivate nucleocapsid transcription prior to packaging, and to mediate nucleocapsid association with the nascent envelope. The M2 protein appears to function as a transcription factor to increase polymerase processivity, and enhance readthrough of intergenic junctions during virus transcription (Hardy et al. 1999; Hardy and Wertz 2000). It has a Cys_3H_1 zinc-binding motif that is essential for its function, and has been shown to interact with the N protein (Hardy and Wertz 2000).

Of the pneumovirus proteins, the function of NS1 and NS2 proteins are the least defined. NS1 and NS2 are considered nonstructural proteins as only trace amounts are detected in the virion (Huang et al. 1985; Collins et al. 1990a; Evans et al. 1996). Unique to pneumoviruses, the nonstructural proteins are encoded by separate mRNAs. NS1 and NS2 may act cooperatively to antagonize interferon (IFN)-α/β-induced antiviral responses, and NS2 protein appears to be rapidly processed and secreted (Schlender et al. 2000; Gotoh et al. 2001). Studies with recombinant RSVs with deletions in the *NS1* and *NS2* have shown that these genes are dispensable for virus replication in vitro; however, they provide auxiliary functions for efficient RSV replication in vitro and in vivo (Jin et al. 2000).

METAPNEUMOVIRUS PROTEINS

The *Metapneumovirus* genus has two members that cause respiratory disease, APV and the recently discovered hMPV (van den Hoogen et al. 2001; Stockton et al., 2002). Similar to the pneumoviruses, electron microscopy and negative staining have shown that metapneumovirus virions are pleomorphic, consisting of a nucleocapsid surrounded by a lipid envelope with a diameter ranging from 150 to 300 mm (Figure 4). APV has similar morphology and structural polypeptides compared with those of bovine, human, and murine pneumoviruses, but lacks the *NS* genes, making the genome shorter (13.3 kb). APV possesses a helical nucleocapsid 14 nm in diameter, and eight viral polypeptides with a gene order given by 3′-*N–P–M–F–M2–SH–G–L*-5′. hMPV has the same gene order.

The APV F glycoprotein consists of 538 amino acids, and the F1 and F2 subunits contain 102 residues (including the F1–F2 connecting peptide RRRR) and 436 residues, respectively. The F glycoprotein protein has approximately 40 percent amino acid identity with the F glycoprotein of RSV (*Pneumovirus* genus), but half that with members of the other two genera (*Respirovirus* and *Morbillivirus*) in the *Paramyxoviridae* family (Njenga et al. 2002). The putative hMPV F glycoprotein open reading frame encodes a 539 amino acid protein. Amino acid sequence analysis indicates 81 percent identity to group C APV, and only 10–20 percent homology with other paramyxovirus counterparts. The F1 and F2 subunits are similar to APV, and contain a conserved cleavage site (RQSR). Interestingly, a second cleavage site (RARR) occurring in RSV does not occur in metapneumoviruses. Similar to pneumoviruses, two heptad repeats (HRA and HRB) are located adjacent to the fusion peptide and transmembrane region, and are required for viral fusion.

The APV *G* gene is 1 193 nt in length and encodes a protein of 391 amino acids, which is larger than the RSV

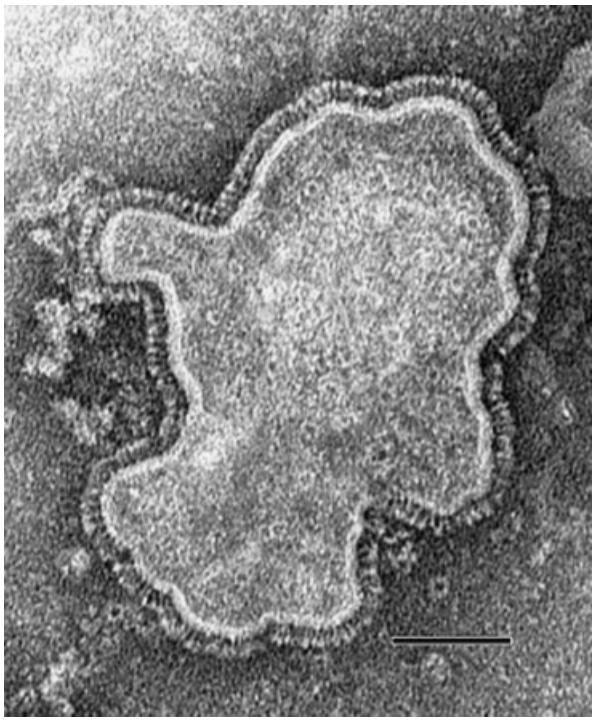

Figure 4 *A negative-stained electron micrograph of hMPV. This pleomorphic form of the virus is stain-penetrated, to permit visualization of portions of the virus envelope and nucleocapsid. A border composed of hMPV surface proteins occurs around the virus periphery. Bar marker represents 100 nm. (Courtesy of Charles Humphrey, Centers for Disease Control and Prevention, Atlanta, GA.)*

G glycoprotein (292–299 amino acids) (Ling et al. 1992). The APV *SH* gene is 589 nt in length, encoding a protein of 174 amino acids that is considerably larger than the RSV SH protein (64 amino acids) (Ling et al. 1992). Hydrophobicity profiles of APV SH and G glycoproteins show considerable similarity to those of the SH and G glycoproteins of RSV. The nucleotide sequences of the putative attachment protein (G glycoprotein) of APV isolates suggests that there are at least two distinct subgroups (A and B), similar to the grouping described for RSV (Juhasz and Easton 1994). Within the subgroups, there is nearly 100 percent amino acid identity; however, between the subgroups, there is considerable divergence. The hMPV *SH* gene encodes a 183 amino acid protein, which is the largest of all pneumovirus or metapneumovirus SH glycoproteins. The amino acid composition and hydrophobicity profile is similar to APV and pneumoviruses; however, hMPV SH glycoprotein contains 10 cysteine residues, compared to 16 for APV. The putative hMPV G glycoprotein open reading frame encodes a 236 amino acid protein. Several smaller open reading frames that lack start codons occur immediately following, or are in frame with, the G glycoprotein open reading frame, suggesting that additional coding sequences are expressed as separate proteins, or are expressed through RNA-editing events. The hMPV G glycoprotein open reading frame is predicted to contain five N-linked glycosylation sites, similar to APV (Juhasz and Easton 1994; Njenga et al. 2002), but lower than RSV which has seven sites (Wertz et al. 1985). The predicted hydrophobicity profile of hMPV G glycoprotein is similar to the pneumoviruses, and the overall organization is consistent with an anchored type II transmembrane protein. However, the hMPV G glycoprotein lacks the cysteine secondary structure and CX3C chemokine motif in the G glycoprotein of pneumoviruses.

The APV nucleocapsid protein gene (*N*) comprises 1 197 nt, forming a single major open reading frame that potentially encodes a protein of 391 amino acid residues (Li et al. 1996). The predicted N protein is identical in length to human, bovine, and ovine RSV, and overall is approximately 41 percent similar, but has some regions of >90 percent identity (Njenga et al. 2002). The hMPV N protein is a 394 amino acid protein similar to APV. Amino acid sequence analysis indicates 88 percent overall identity to group C APV, but only 10 percent overall identity with other paramyxoviruses.

The APV phosphoprotein gene (*P*) comprises 855 nt containing one open reading frame encoding a protein of 278 amino acids (Ling et al. 1995). Comparison of the overall APV P protein sequence with that of the other pneumoviruses reveals amino acid identities ranging from 31 to 35 percent; however, there is much higher identity (approximately 70 percent) in a region of 57 residues that include a heptad repeat sequence. The putative hMPV P protein open reading frame encodes a 294 amino acid protein that shares 68 percent amino acid homology to group C APV. Similar to RSV and group C APV, the hMPV P protein open reading frame lacks cysteine residues.

The APV large viral polymerase gene (*L*) comprises 6 099 nt, and encodes a single major open reading frame of 2 004 amino acids (Randhawa et al. 1996). The APV L protein is the smallest described for any nonsegmented, negative-strand RNA virus. The protein contains six linear noncontiguous domains, a consensus ATP-binding site, and four polymerase motifs previously described for the L proteins of negative-strand RNA viruses. The *L* gene of hMPV encodes a 2 005 amino acid protein, and contains a consensus ATP-binding motif. Domain III in the hMPV L protein (amino acids 625–847) has 83 percent amino acid sequence identity with APV, and approximately 70 percent identity with RSV.

The APV M protein contains a hydrophobic domain common to pneumoviruses (Seal 1998). The M protein nucleotide sequence of group A strains is approximately 75 percent similar to group B strains (Seal 2000). The APV *M2* gene contains two overlapping open reading frames that encode the M2-1 protein of 184–186 and 71–73 amino acids that do not show any similarity to the equivalent RSV protein. The sequences of the intergenic regions of APV reveal the gene order to be 3′-*M–F–M2*-5′,

compared to the 3′-*M–SH–G–F–M2*-5′ gene order of pneumoviruses. Determination of the nucleotide sequences in APV has established that *NS1* and *NS2* genes are absent in APV. The hMPV *M* gene, like APV, has two overlapping open reading frames, the first of which encodes a 187 amino acid M2-1 protein having 84 percent sequence identity to group C APV, the second of 71 amino acids. The hMPV M2-1 protein has three cysteine residues located within the first 30 amino acid residues conserved among all pneumoviruses, suggesting the possibility of a zinc-binding protein. Amino acid sequence comparison of the M2-2 open reading frame indicates approximately 60 percent identity to group C APV.

POLYMORPHISMS AMONG PNEUMOVIRUS AND METAPNEUMOVIRUS

The genomic organization of pneumoviruses and metapneumovirus are comparable, but there are distinct variations. Pneumovirus genomes (15.2 kb) contain two nonstructural genes (*NS1* and *NS2*), followed by the nucleocapsid (*N*), phosphoprotein (*P*), matrix (*M*), small hydrophobic (*SH*), surface glycoprotein (*G*), fusion (*F*), second matrix (*M2*), and large RNA-dependent, RNA polymerase (*L*) genes. By contrast, metapneumovirus genomes are smaller (13.4 kb), lack *NS1* and *NS2* genes, and the gene order is 3′-*N–P–MF–M2–SH–G–L*-5′. Genetic and antigenic polymorphisms are well documented for pneumoviruses such as RSV, where the *SH* and *G* genes have been shown to have the greatest diversity among strains (Sullender et al. 1990, 1991, 1998; Mlinaric-Galinovic et al. 1994; Zheng et al. 1999). For RSV A and B strains, there is approximately 25 percent antigenic relatedness overall, with F glycoproteins approximately 50 percent related and G glycoproteins approximately 1–10 percent related (Johnson et al. 1987a; Hendry et al. 1988). Divergence in the G glycoprotein is greatest in the ectodomain and related to poorly conserved *N*- and *O*-linked sugar acceptor sites (Johnson et al. 1987b; Sullender et al. 1991). A high percentage of nucleotide sequence differences occur in the G glycoprotein for A and B strains, for which nearly half encode amino acid substitutions (Cane et al. 1991; Sullender et al. 1991). It is possible that G glycoprotein diversity among RSV strains provides an advantage to the virus to evade previously induced immunity in the population. Sequence information indicates that multiple genotypes circulate simultaneously in the same community, and similar genotypes circulate in widely separated communities during different years (Peret et al. 1998, 2000). Immune pressure may contribute to diversity in the G glycoprotein, since it is one of the two major neutralizing antigens (the other the F glycoprotein), the ectodomain is extracellular, and sequence diversity is correlated with antigenic diversity.

Metapneumoviruses such as APV appear to have similar genetic and antigenic polymorphisms as the pneumoviruses. Comparison of the nucleotide and amino acid sequences of APV isolates indicate that the G glycoprotein is extremely variable between strains (38 percent nucleotide identity and 56 percent amino acid predicted sequence identity), but there is high nucleotide sequence identity (>99 percent) among strains (Bayon-Auboyer et al. 2000; Seal 2000; Njenga et al. 2002). APV strains also vary in patterns of neutralization by monoclonal antibodies reactive to the G glycoprotein (Njenga et al. 2002). Similar to RSV, the F glycoprotein and M protein of APV have extensive nucleotide and amino acid sequence identity within strains, but lower identity between strains (Naylor et al. 1998; Seal 2000; Seal et al. 2000). Sequence comparison between hMPV and APV shows high levels of nucleotide identity, and absence of *NS1* and *NS2* genes. Partial N, M, F, and L sequence comparison of hMPV isolates indicates that hMPV has two strains or clusters with 90–100 percent nucleotide identity within strains, and 80–90 percent identity between strains. Comparison of the four strains of APV to hMPV indicates 56–88 percent amino acid sequence identity within the nine open reading frames, and comparison of N, P, M, F, and M2 proteins indicated 80 percent overall amino acid identity. The APV *G* gene sequence is currently unavailable, but partial sequence information (personal communication) suggests that it has low sequence identity to hMPV.

VIRUS REPLICATION

Virions primarily attach to cells through the G glycoprotein. Attachment appears to be principally mediated by interaction of heparin-binding domains on the G glycoprotein with cell surface glycosaminoglycans (Krusat and Streckert 1997; Bourgeois et al. 1998; Feldman et al. 1999). However, recent evidence indicates that a CX3C chemokine motif located in the conserved region of the G glycoprotein (amino acids 182–186) may facilitate attachment through interaction with the CX3C chemokine receptor, CX3CR1 (Tripp et al. 2001), although this region is not required for attachment (Teng and Collins 2002). The G glycoprotein itself is not required for virion attachment to cells. Mutant RSV lacking *SH* and/or *G* genes have been shown to infect cells, likely through interaction with the F glycoprotein (Karron et al. 1997a; Teng et al. 2001; Techaarpornkul et al. 2002). Pneumoviruses penetrate cells by fusion with the plasma membrane, a process associated with the F glycoprotein (Bachi 1988). Penetration involves incorporation of the viral envelope into the cell membrane, and nucleocapsid release into the cytoplasm (Levine and Hamilton 1969; Hierholzer and Tannock 1986; Routledge et al. 1987; Arslanagic et al. 1996). The L protein initiates viral transcription and replication proceeds in the cytoplasm without nuclear involvement (Fearns and Collins 1999).

Transcription of pneumovirus mRNAs occurs in a 3′ to 5′ order from a single promoter near the 3′ end. Polymerase-mediated transcription results in a series of subgenomic mRNAs that are co-linear copies of the genes with no evidence of mRNA editing or splicing (Dickens et al. 1984; Huang et al. 1985; Kuo et al. 1996; Harmon et al. 2001; Krempl et al. 2002). Sequence and transcriptional mapping analysis of RSV mRNAs indicates that each transcript begins at the first nucleotide of the gene-start signal, is capped at the 5′ end, and polyadenylated at the 3′ end. Both mRNAs and proteins can be detected by 4 hours post-infection with peak mRNA synthesis and protein expression occurring 16–20 hours post-infection. The level of protein expressed is related to mRNA abundance (Dickens et al. 1984). In general, there is decreasing amounts of mRNAs with increasing gene distance from promoter sequence. RNA replication is dependent on active protein synthesis.

VIRUS ASSEMBLY

Virions assemble at the plasma membrane. Inclusion bodies containing viral ribonucleoprotein cores appear immediately below the plasma membrane. Nucleocapsids localize with cell membrane containing membrane viral glycoproteins. Virions mature in clusters at the apical surface in a filamentous form associated with caveolin-1, and extend from the plasma membrane (Brown et al. 2002). Experiments using human primary airway epithelial cell cultures have shown that ciliated epithelial cells are targeted by RSV, and that infection and shedding occurs via the apical membrane, and virus may be spread to neighboring ciliated cells by the motion of the cilia (Zhang et al. 2002).

INFECTION AND EXPERIMENTAL ANIMAL MODELS

Pneumoviruses and metapneumoviruses generally infect the superficial layers of the respiratory epithelium, but can grow in a wide variety of mammalian cells. There appear to be few differences in susceptibility to infection for most epithelial cell types, but significant differences in virus replication. For example, human nasal epithelial cell cultures, human bronchial epithelial cell cultures, and a human bronchoepithelial cell line (BEAS-2B) are equally susceptible to RSV infection; however, bronchial cells release less infectious virions than nasal cells (Becker et al. 1992), and RSV replicates better in ciliated epithelial cells compared to non-ciliated epithelial cells (Henderson et al. 1978; Zhang et al. 2002). In addition, a human epithelial cell line, HEp-2, and an African green monkey cell line, Vero, are commonly used to propagate pneumoviruses; however, only Vero cells effectively support metapneumovirus propagation (van den Hoogen et al. 2001). APV has been successfully isolated from infected turkeys using day-old chicken or turkey embryos, and chicken embryo fibroblasts and Vero cells support virus replication (Yachida et al. 1978; Goyal et al. 2000; Jirjis et al. 2002b; Patnayak et al. 2002).

Viral infection of susceptible cell lines results in a majority of cell-associated virions. A large fraction of the cell-associated virions are aggregated, and many virions released from the infected cell are defective and non-infectious (Levine and Hamilton 1969; Bachi 1988). Both pneumoviruses and metapneumoviruses are rather unstable, and rapidly lose infectivity during storage at −70°C, during handling, and during purification procedures. Freezing virus stocks in media containing 50 mM HEPES and 100 mM magnesium sulfate tends to stabilize the virions. Plaque assays can be used to readily quantify pneumoviruses; however, metapneumoviruses do not mediate quantifiable cytopathology or plaque formation (van den Hoogen et al. 2001). This limitation can be overcome by acetone fixation of infected cells and immunostaining to quantitate infected cells.

For pneumoviruses, a variety of experimental animals may be useful for experimental evaluation of infection or disease pathogenesis; however, there is great variation in permissiveness to infection. For RSV, the only experimental animal that approaches human permissiveness to infection and disease is the chimpanzee (Belshe et al. 1977; Collins et al. 1990b). Since this animal model is limited, the majority of RSV studies have focused on mice and cotton rats, which are semipermissive for RSV replication, but fail to fully emulate RSV disease associated in humans (Byrd and Prince 1997). BALB/c mice are the most commonly used experimental animal model for RSV infection, and much has been learned from its use; however, they appear less permissive to RSV infection than cotton rats (Prince et al. 1978, 1979, 1986). Histopathological studies of RSV disease in cotton rats has shown to better emulate the human condition than similar studies in mice. The choices for experimental animal models of metapneumovirus infection are less diverse. hMPV appears to be primarily a human pathogen; however, recent studies from our laboratory have shown that hMPV can infect and replicate in BALB/c mice, and there is strong preliminary evidence that cotton rats are also susceptible to infection (personal communication). APV is a pathogen of a variety of birds including turkeys, ducks, pheasants, and ostriches causing rhinotracheitis, and possibly a pathogen of chickens associated with swollen head syndrome (Cook 2000; Catelli et al. 2001; Shin et al. 2001).

DISEASE PATHOGENESIS

RSV is the leading cause of severe lower respiratory tract infection in infants and young children worldwide (Simoes 1999; Hall 2001; Krilov 2001; Law et al. 2002; McNamara and Smyth 2002; Weisman 2002), and may

lead to a wide spectrum of respiratory illnesses. RSV infection is most common during infancy and early childhood (CDC 2000), but may also occur in adults, the immune compromised, and the elderly (Englund et al. 1991; Couch et al. 1997; Hall 1999; Han et al. 1999; Simoes 1999; Falsey and Walsh 2000). In infants, 25–40 percent of infections result in lower respiratory tract involvement, including pneumonia and bronchiolitis (Shay et al. 1999; Hall 2001). Viral replication initiates in the upper respiratory tract; however, it can spread to the lower airways by aspiration of secretions or via the respiratory epithelium involving the bronchi, bronchioles, and alveoli, and may continue to macrophages and monocytes (Domurat et al. 1985; Midulla et al. 1989; Becker et al. 1992). Infection is associated with necrosis of the bronchiolar epithelium, destruction of the ciliated epithelial cells, and a peribronchiolar infiltrate of lymphocytes and mononuclear cells (Price 1990; Lugo and Nahata 1993). Interalveolar thickening and filling of alveolar spaces with fluid released from edematous submucosal and advential tissues may lead to airways obstruction (Price 1990; Panitch et al. 1993). The characteristics of the immune response to RSV are not fully elucidated, and it is possible that damage of the epithelium and the bronchiolar ciliary cells may be associated with the host immune response, particularly RSV-specific $CD8^+$ cytotoxic T cells (CTL) (Garofalo et al. 1996).

RSV illness frequently begins with rhinorrhea and low-grade fever that is often accompanied by cough and wheezing (Price 1990; Lugo and Nahata 1993). At the beginning of illness, RSV replicates in the nasopharynx, reaching titers between 10^4 and 10^6 $TCID_{50}$/ml of nasal secretion in infants (Hall et al. 1975, 1976; Hall 1977). The titer deceases over time, and most patients recover within 1–2 weeks post-infection. Some infants continue to shed virus for 3 weeks after hospitalization, and disease severity may correlate with the duration of virus shedding (Hall et al. 1976). Approximately 60 percent of primary RSV infections are confined to the upper airways; however, during a period of 2–5 days, infection may progress to lower respiratory tract involvement. The mechanism for viral spread to the lower airways is not known, but may occur by epithelial ciliary action, or through aspirated secretions; however, RSV can spread cell to cell without emerging into the extracellular space. Severe disease generally involves lower respiratory tract infection, and physical examination may reveal otitis media, rales, and diffuse wheezing (Anderson 2000; Greenberg 2001; Panitch 2001; West 2002). The severity of the disease is directly related to the age of the patient. Infants under 6 months of age are the most severely affected, likely due to smaller, more easily obstructed airways and decreased ability to clear secretions. Illness may be particularly severe in premature infants, and in those with congenital cardiac or pulmonary disease (Krilov 2001; Shay et al. 2001; Aujard and Fauroux 2002; Law et al. 2002). Apnea occurs in approximately 20 percent of infants hospitalized with RSV bronchiolitis (Bruhn et al. 1977; Church et al. 1984). The frequency of apnea increases significantly in premature infants, occurring early in the course of RSV disease. Apnea rarely lasts more than a few days, but about 10 percent of these patients require intubation and mechanical ventilation. The mechanisms that contribute to apnea are not well understood, but recent studies in mice suggest a link between RSV G glycoprotein binding to the CX3C chemokine receptor, CX3CR1, induction of the tachykinin, substance P, and subsequent depression of respiratory rates (Tripp et al. 2003).

In adults, the most common symptoms of RSV infection are those of the common cold which include rhinorrhea, sore throat, and cough. In the elderly, RSV may cause significant lower respiratory tract disease including pneumonia and some mortality (Han et al. 1999; Falsey and Walsh 2000). RSV is also a significant cause of morbidity and mortality in patients undergoing bone marrow or organ transplantation (Wendt 1997; Billings et al. 2002; Ison and Hayden 2002; Small et al. 2002). RSV reinfections occur frequently and are often associated with illness (Henderson et al. 1979); however, the cumulative effect of multiple re-infections appears to temper subsequent disease, an effect that is likely related to developing immunity. The severe disease observed in immune compromised or suppressed patients, and in experimental animal models, indicates that cell-mediated immunity is an important mechanism of host defense against RSV (Fishaut et al. 1980; Graham et al. 1991).

DIAGNOSIS

Parainfluenza viruses and bacteria that can cause respiratory tract illness complicate the diagnosis of RSV infection in infants less than 6 months of age. Presumptive diagnosis of RSV infection in young children can be made on the epidemiologic setting that includes seasonality and community outbreaks of diagnosed RSV infection. The specific diagnosis is established by isolation of RSV from respiratory secretions, including sputum, throat swabs, or nasopharyngeal washes. Infections in older children and adults cannot be differentiated with certainty from those caused by other respiratory viruses. Examining increases in titer of neutralizing serum antibodies may aid diagnosis of RSV infection in older children and adults; however, serological tests depend on fourfold or greater rises in complement-fixing or neutralizing antibody titers for useful diagnosis, and are less sensitive in children under 4 months of age (Richardson et al. 1978; Brandenburg et al. 1997). In addition, serological diagnosis requires comparison of acute and convalescent phase serum specimens, and is therefore not useful during acute illness. Virus obtained through sputum, throat swabs, or nasopharyngeal washes

can be detected by tissue culture and immunostaining, by immunofluorescence, ELISA, or other techniques including detection of nucleic acid by reverse-transcriptase polymerase chain reaction (RT-PCR) (Paton et al. 1992; Falsey et al. 2002; Coiras et al. 2003).

MANAGEMENT AND TREATMENT

Infection with RSV is usually self-limiting, but may require supportive care including administration of oxygen, intravenous hydration, and intubation. Bronchodilators may be used if wheezing is part of the clinical presentation. Inhaled salbutamol may have some beneficial effects as a bronchodilator in moderate bronchiolitis (Kellner et al. 1996); however, racemic epinephrine appears to substantially improve airway resistance and clinical scores (Sanchez et al. 1993). Steroids, which are effective for alleviating wheezing in asthma, appear to have limited beneficial effect in RSV bronchiolitis (Roosevelt et al. 1996; De Boeck et al. 1997). The only specific antiviral drug licensed for RSV treatment is ribavirin. Ribavirin, a guanosine analogue, has antiviral activity in tissue culture and cotton rats (Hruska et al. 1982), but its effectiveness in decreasing the severity of clinical symptoms in young patients is questionable. When delivered as a continuous aerosol, ribavirin appears to have modest effects on the duration of virus shedding (Hall et al. 1983, 1985; Taber et al. 1983), but its use is now recommended only for immune compromised patients and those who are severely ill.

To prevent or reduce severe lower respiratory tract infection by RSV, prophylactic or therapeutic treatment with purified human intravenous immunoglobulin (Ig)G, RSV-IVIG (RespiGAM™), or humanized anti-F glycoprotein monoclonal antibody, palivizumab (Synagis™) has been investigated. RespiGAM™, given parentally (2 g/kg/day) to infants and young children with RSV bronchiolitis or pneumonia was shown to reduce the amount of RSV shed; however, the mean duration of hospitalization was not affected by treatment (Hemming et al. 1987). However, RespiGAM™ given monthly by intravenous infusion has been shown to reduce RSV-associated hospitalization by approximately 40 percent, and significantly reduced the severity of symptoms in high-risk patients who acquired RSV (Groothuis et al. 1993; Simoes et al. 1998). Synagis™ exhibits neutralizing activity and, like RespiGAM™, if administered monthly (15 mg/kg) has been shown to reduce RSV-associated hospitalization by approximately 55 percent (CDC 1998). Since monthly treatment with RespiGAM™ or Synagis™ appears necessary to reduce RSV-associated hospitalization, other agents that may be used in conjunction with these treatments to ameliorate RSV-associated disease are being investigated. Recent studies examining prophylactic or therapeutic treatment of RSV-infected BALB/c mice with neutralizing anti-F glycoprotein and anti-substance P monoclonal antibodies have shown that prophylactic or therapeutic treatment with anti-substance P antibodies promptly reduces pulmonary inflammation, while anti-F antibody treatment reduces the virus load (Haynes et al. 2002), suggesting that combined antiviral and anti-inflammatory (substance P) antibody treatment may be effective in treating RSV disease in humans.

Small molecule inhibitors of RSV infection or replication have received some attention, particularly drugs that target the fusion process. Some peptide fusion inhibitors have been designed to interfere with heptad repeat domains in the F glycoprotein and disrupt their interaction, required during conformational rearrangement of the F glycoprotein that occurs in the later stages of the fusion process (Shigeta 2000; De Clercq 2002). A small-molecule inhibitor of RSV fusion is a peptide comprising amino acids 77–95 of RhoA (Pastey et al. 1999, 2000). RhoA is a small GTP-binding protein that has been shown to mediate virus-induced syncytium formation (Pastey et al. 1999, 2000; Gower et al. 2001). In studies of mice, in vivo administration of the RhoA peptide was shown to be effective in decreasing RSV titers if given at the time of infection; however, treatment at 4 days post-RSV infection was less effective at reducing viral titers, and did not alter the degree of pathogenesis when compared to mice treated with phosphate-buffered saline (PBS) alone. A similar picture has emerged for a variety of other small-molecule inhibitors that appear to be effective at inhibiting RSV infection in vitro, but their solubility, bioavailability, and effectiveness in vivo remains to be elucidated.

VACCINE DEVELOPMENT

RSV infection may cause severe lower respiratory tract infections early and late in life, and repeat infections with the same, or different strains of RSV are common. These indications suggest a lack of durable immunity. For an RSV vaccine to be effective, it must confer protection better than that associated with natural RSV infection, and for infants, must do so in the first weeks of life. These obstacles may require different vaccines and vaccination strategies. Early attempts to develop a safe and effective RSV vaccine failed. A formalin-inactivated, alum-precipitated RSV (FI-RSV) vaccine preparation that was administered intramuscularly to young children in an RSV vaccine trial in 1969 was not protective and when vaccinated children were subsequently exposed to natural RSV infection, they developed enhanced pulmonary disease with several fatalities (Kapikian et al. 1969; Kim et al. 1969). The enhanced pulmonary disease has been attributed to altered immunity to the FI-RSV vaccine; however, the exact mechanism is not completely understood. Recent studies from our laboratory examining FI-RSV-enhanced disease have shown that the absence of the G glycoprotein or G glycoprotein CX3C motif during FI-RSV

vaccination or RSV challenge of FI-RSV-vaccinated mice, or treatment with anti-substance P or anti-CX3CR1 antibodies, reduces or eliminates enhanced pulmonary disease, modifies T-cell receptor (TCR) Vβ usage, and alters CC and CXC chemokine expression by pulmonary leukocytes (Haynes et al. 2003). These results suggest that the G glycoprotein, and in particular the G glycoprotein CX3C motif, may be key in the enhanced inflammatory response to FI-RSV vaccination, possibly through the induction of substance P.

The disastrous results associated with FI-RSV vaccination were unexpected since natural RSV infection induces a protective although incomplete immune response to infection. Thus, RSV vaccine efforts have been focused on development of attenuated vaccines. Development of temperature-sensitive or cold-passaged vaccine candidates and subsequent examination in adults indicated some effectiveness, but the attenuated vaccine candidates proved too unstable or virulent in children, and often reverted back to wild-type virus (Pringle et al. 1993; Karron et al. 1997b; Crowe et al. 1999; Gonzalez et al. 2000; Wright et al. 2000; Crowe 2001b; Krilov 2001). Clinical trials with candidate subunit vaccines have been explored. A series of trial studies examined the effectiveness of a full-length F glycoprotein vaccine (PFP) purified from RSV-infected cells (Paradiso et al. 1994; Tristram et al. 1994; Falsey and Walsh 1996; Dudas and Karron 1998; Groothuis et al. 1998; Gonzalez et al. 2000). An indication from the studies suggested that PFP was safe, but was only moderately immunogenic. A different series of clinical trials examined the effectiveness of a recombinant protein (BBG2Na) consisting of amino acids 13–230 of the RSV G glycoprotein fused to the C-terminal domain of streptococcal G protein (Libon et al. 1999; Kneyber et al. 2000; Goetsch et al. 2001; Power et al. 2001). These studies showed that BBG2Na was moderately immunogenic in adults, but did not offer significant protection. Investigation of other candidate subunit vaccines is proceeding, including development of DNA vaccines. Effective subunit vaccines may be useful in RSV seropositive groups at high risk, or immunizing pregnant women to enhance protection of their newborns (Crowe 2001b; Kneyber and Kimpen 2002).

Reverse genetics employing full-length RSV complementary DNA to produce transcripts of infectious RNA offers many advantages in RSV vaccine design. The entire RSV genome can be precisely manipulated to offer optimal immunogenicity and attenuation. Reverse genetics has been used to delete nonessential genes in the RSV genome with the hope of restricting replication in vivo, but not in vitro, thus permitting efficient vaccine production (Collins and Murphy 2002). Studies with recombinant RSV have shown that five RSV genes, *NS1*, *NS2*, *SH*, *G*, and *M1*/*M2* can be deleted or silenced individually, or in certain combinations, without dramatically altering viral replication in vitro (Collins and Murphy 2002). Attenuation studies in chimpanzees have shown that recombinant RSV lacking the *SH* gene is least attenuated, whereas recombinant RSV lacking the *M2* gene is most attenuated (Teng et al. 2000). Attenuation of RSV vaccine candidates may also be achieved by taking advantage of the natural host restriction of RSV (Buchholz et al. 2000). Bovine RSV is over-attenuated and poorly immunogenic in seronegative chimpanzees (Buchholz et al. 2000); however, bovine RSV replication and immunogenicity can be improved by replacing the *F* and *G* genes with human RSV *F* and *G* genes (Schmidt et al. 2002). Strategies that focus on systemic replacement or deletion of RSV or bovine RSV genes in chimeric recombinant RSV are anticipated to yield useful vaccine candidates. Another advantage of recombinant RSV is the ability to alter or silence regions that may be associated with altered immunity or pathogenesis. For example, the RSV G glycoprotein has been shown to contain a CX3C chemokine motif (amino acids 182–186) that can bind to the CX3C chemokine receptor, CX3CR1, and mediate leukocyte chemotaxis in a fashion similar to fractalkine (Tripp et al. 2001). Recent studies from this laboratory suggest that the G glycoprotein, and in particular the G glycoprotein CX3C motif, is key in the enhanced inflammatory response to FI-RSV vaccination, possibly through the induction of substance P (Haynes et al. 2003). Therefore, ablation of this region may enhance the efficacy of recombinant RSV vaccine candidates.

IMMUNOLOGY AND HOST FACTORS

Innate immunity is the first line of defense providing early resistance to virus infection through a variety of host components. For respiratory viruses, innate immunity may be first mediated by mucus secreted by the membranes lining respiratory tract. Mucus acts as a protective barrier to block the adherence of respiratory viruses to epithelial cells, and ciliary movement, coughing, and sneezing removes virus particles trapped within mucus. In addition, a family of proteins called collectins has the ability to recognize foreign carbohydrate patterns, interact with phagocytic cells, and induce opsinization of the particles containing foreign carbohydrates (Lu et al. 2002; Shepherd 2002). The collectins, especially mannose-binding protein, and alveolar surfactant molecules SP-A and SP-D, are important agents in innate immunity (McCormack and Whitsett 2002), and SP-A is important in innate immunity to RSV infection (LeVine et al. 1999). SP-A binds to the RSV F glycoprotein, but not to the G glycoprotein, and neutralizes RSV infection in a calcium-dependent fashion (Ghildyal et al. 1999). If viruses penetrate to the respiratory epithelium, destructive soluble factors including enzymes and cytokines are released by the infected cells, or by resident phagocytic cells. Infected epithelial cells and alveolar macrophages release chemokines and pro-inflammatory

cytokines that include tumor necrosis factor (TNF)-α, interleukin (IL)-1, IL-6, and CC and CXC chemokines (Becker et al. 1991; Arnold et al. 1995; Saito et al. 1997; Zhang et al. 2001). Expression of these soluble mediators of immunity contributes to airway inflammation, immune cell trafficking, bronchial hyperresponsiveness, and exacerbates mucus production. The CC chemokines, such as the macrophage inflammatory proteins (MIP), regulation on activation, normal T-cell expressed and secreted (RANTES), and eotaxin recruit a variety of granular cells to the site of infection or inflammation (Saito et al. 1997; Olszewska-Pazdrak et al. 1998). RANTES, eotaxin, and MIP-1α are potent chemokines for eosinophils and increased levels, or mRNA, in airway secretions or peripheral blood leukocytes have been found in infants with RSV bronchiolitis (Hornsleth et al. 2001; Noah et al. 2002; Smyth et al. 2002; Tripp et al. 2002). The CXC chemokine IL-8, a potent chemoattractant of neutrophils, has been found in secretions of RSV-infected children (Sheeran et al. 1999; Noah et al. 2002; Smyth et al. 2002), and experimentally infected adults (Noah and Becker 2000). Eosinophils are part of the nonspecific innate immune response and participate in inflammatory reactions. They contain cationic molecules that are useful for destroying infectious agents, especially helminths. Neutrophils are nondividing, short-lived cells containing primary azurophilic granules and secondary granules. The primary azurophilic granules contain myeloperoxidase together with other antimicrobial agents including defensins and cathepsin G. The secondary granules contain lactoferrin and other enzymes. Alveolar macrophages and dendritic cells are long-lived, tissue-resident cells that have an important role in phagocytosis and antigen presentation to the T-cell compartment. In this role they recognize and remove virally infected epithelial cells and debris, and present viral antigen to T cells, thereby initiating the adaptive immune response. Contact with virally infected cells, and the process of phagocytosis, activates macrophages and dendritic cells to secrete soluble mediators including interferons, lysozyme, and other factors that inhibit viral replication and upregulate the inflammatory response (Krilov et al. 1987; Lewis et al. 1989; Tsutsumi et al. 1996). Recognition of pathogens by phagocytic cells is achieved by pattern recognition receptors encoded in the germline (Hallman et al. 2001; Armant and Fenton 2002). The pattern recognition receptors (PRR) have broad specificity and recognize pathogen-associated molecular patterns (PAMP) that differ from pathogen to pathogen, but are not found in the host (Underhill and Ozinsky 2002). Thus, PAMPs are perceived as molecular signatures of infection by PRRs, resulting in activation of innate and adaptive immune responses (Barton and Medzhitov 2002; Sabroe et al. 2002). There are two major groups of PRRs – those that are secreted in the blood and lymph, and those on the surface of cells. Secreted PRRs include components of the complement fixation pathway, e.g. C2, C3, and C4, and cell-surface PRRs include the Toll-like receptors (TLR) (Akira et al. 2001). There are 10 known TLRs, and three other candidate molecules, that specialize in recognition of different PAMPs. For example, TLR2 generally recognizes peptidoglycan of gram-positive bacteria, while TLR4 generally recognizes lipopolysaccharide in the outer membrane of gram-negative bacteria (Akira et al. 2001). Interestingly, the RSV F glycoprotein has been shown to stimulate innate immunity through activation of the shared components of CD14 and TLR4 (Kurt-Jones et al. 2000), and TLR4 appears to be important in the innate immune response to RSV infection (Haynes et al. 2001). TLR4-deficient mice challenged with RSV exhibit impaired natural killer (NK) cell and $CD14^{+}$-cell pulmonary trafficking, deficient NK-cell function, impaired IL-12 expression and impaired virus clearance. Activation of TLRs on phagocytic cells can trigger adaptive immune responses by up-regulation of T-cell co-stimulatory molecules and cytokines required for T-cell activation. In this role, phagocytic cells, particularly dendritic cells, have a key role in coupling innate and adaptive immune responses.

The adaptive immune response includes humoral and cell-mediated immunity. Antibodies located in the serum, lymphatics, and in secretory pathways mediate humoral immunity. There are five different classes of antibodies or immunoglobulins (Ig) known as IgD, IgA, IgM, IgE, and IgG, four subclasses of IgG, and two subclasses of IgA. Soluble antibodies and those on the surface of B cells recognize antigens in the native form. Resistance to respiratory virus infection in the upper airways is mediated by local, secretory IgA, and is transitory. More durable humoral resistance to infection seems to be associated with IgM, and especially IgG antibodies. In the newborn, passively acquired maternal IgG antibodies provide some protection from infection, a factor that may contribute to the reason why children under 8 weeks of age are rarely infected with RSV (Crowe 2001a). Maternal antibody levels diminish during the first 6 months of life (Brandenburg et al. 1997), leaving infants unprotected against RSV infection; however, serum and secretory antibodies appear within days of a primary RSV infection (McIntosh et al. 1978; Welliver et al. 1980). The serum and secretory antibody titers produced in infants are significantly lower than those of older subjects (Murphy et al. 1986a; de Sierra et al. 1993), and wane several months after primary infection of infants (Welliver et al. 1980). The diminished serum and neutralizing antibody response has been attributed to suppressive effects of maternally transferred antibodies (Crowe 2001a; Wright et al. 2002); however, immunological immaturity may also be important. Post-infection, serum antibody levels generally wane; however, higher levels are maintained over a longer period after repeated RSV infection (Murphy et al. 1986b; Wagner et al. 1989). As the infant matures,

the presence of neutralizing IgA in respiratory secretions produced by local mucosal B cells may become more important. Studies of experimentally induced RSV disease in healthy adult volunteers indicate that the presence of nasal IgA neutralizing antibody correlates more closely with protection than does the presence of serum antibody (Mills et al. 1971). Complement is an important component of innate immunity and the humoral response to RSV infection. RSV-infected epithelial cells can activate complement by both the classical and alternative complement pathways (Edwards et al. 1986; Smith et al. 1981), and complement is important for enhanced antibody-mediated virus neutralization.

Cell-mediated immunity to respiratory virus infection involves $CD8^+$ CTLs, $CD4^+$ helper T cells, and innate immune cells, e.g. NK cells. The role of cell-mediated immunity in virus clearance is difficult to assess in humans; however, studies in patients with deficiencies in cellular immunity have shown that cellular immunity has a pivotal role in protection from severe RSV disease and limiting virus shedding (Fishaut et al. 1980; Chandwani et al. 1990). In vitro studies of human peripheral blood mononuclear cells (PBMC) have shown that NK cells and $CD4^+$ and $CD8^+$ T cells have potent antiviral responses. Exposure of adult PBMC to RSV immediately up-regulates NK activity, a feature dependent upon IL-15 induction (Fawaz et al. 1999). Infants hospitalized because of RSV infection have increased numbers of $CD16^+/CD56^+$ NK cells, and express T-helper-1 (Th1) and T-helper-2 (Th2) cytokines, and enhanced CC chemokine messenger RNA (Tripp et al. 2002). Antibody-dependent cellular cytotoxicity (ADCC), a feature associated with NK cells has been detected in human PBMC from RSV-infected individuals using serum antibodies and antibodies from nasopharyngeal secretions (Scott et al. 1977; Meguro et al. 1979; Cranage et al. 1981; Kaul et al. 1982). RSV-specific CTL responses in PBMC from infants with acute RSV infection can be detected rapidly after infection (Isaacs et al. 1987; Chiba et al. 1989). The response is age-dependent, as >65 percent of infants 6–24 months of age, and approximately 35 percent of infants under 5 months of age exhibit RSV-specific cellular cytotoxicity. Examination of the CTL repertoire of adults to RSV proteins showed that N, SH, F, M, M2 and NS2 proteins are targeted by CTLs with no predilection toward a particular major histocompatibility complex (MHC) phenotype (Bangham et al. 1986; Cherrie et al. 1992). Most data concerning RSV-specific $CD4^+$ or $CD8^+$ T-cell responses are derived from experimental animal studies, as it is difficult to assess responses in the lungs of infected patients, particularly infants and young children. Examining alterations of $CD4^+$ or $CD8^+$ T-cell responses in PBMC may be useful as a correlate of immune status; however, studies that examine bronchial lavage cells from infants infected with RSV may provide better information. For example, a study that examined bronchial lavage cells from infants infected with RSV identified large numbers of neutrophils in the upper airway (93 percent) and lower airway (76 percent), but few $CD4^+$ and $CD8^+$ T cells with median $CD4^+/CD8^+$ ratios being 22:1 in the upper airway, and 15:1 for the lower and upper airways (Everard et al. 1994). These results suggest that neutrophils probably have a major role in immunity and possibly RSV disease, and counter the hypothesis that excessive lymphocyte cytotoxicity is associated with RSV bronchiolitis.

The role of $CD4^+$ and $CD8^+$ T lymphocytes in terminating RSV infection, causing disease, and protecting from re-infection have been investigated using experimental animal models, particularly BALB/c mice. In BALB/c mice, the M2, F, and N proteins are the major targets for CTLs (Nicholas et al. 1990; Openshaw et al. 1990; Openshaw 1995b). Both $CD4^+$ and $CD8^+$ T-cell subsets have been shown to be involved in terminating RSV replication, as antibody depletion of both T-lymphocyte subsets markedly prolongs RSV replication (Graham et al. 1991). In addition, both $CD4^+$ and $CD8^+$ T cells have been shown to contribute to immunity and disease pathogenesis, although $CD8^+$ T cells appeared to have a dominant role in controlling RSV disease (Varga and Braciale 2002). Investigation of the RSV proteins associated with host resistance has shown that sensitization with F or G glycoproteins induces almost complete resistance to RSV challenge despite depletion of both $CD4^+$ and $CD8^+$ T cells prior to challenge, indicating that host resistance is mediated by the humoral response to F or G glycoproteins (Connors et al. 1992a). However, host resistance may also be mediated by sensitization with the M2 protein, and depletion of $CD8^+$ T cells abrogates M2-associated protection, while depletion of $CD4^+$ T cells has an intermediate effect (Connors et al. 1992a). Although both $CD4^+$ and $CD8^+$ T cells contribute to disease pathogenesis, passive transfer of RSV-specific $CD4^+$ T cells into RSV-immune mice mediates more severe immunopathology and pulmonary eosinophilia compared to transfer of $CD8^+$ T cells (Alwan et al. 1992). Distinct types of pulmonary disease are mediated by functionally different T-cell subsets reactive to different RSV proteins. Adoptive transfer of T-cell lines recognizing G glycoprotein into RSV-infected mice induces severe illness, characterized by pulmonary eosinophilia and hemorrhaging, compared to transfer of M2-specific, or F-glycoprotein-specific T-cell lines (Alwan et al. 1994). It is likely that Th2-type cytokine expression by the G-glycoprotein-specific T-cell lines contributed to the disease severity, since these cells were $CD4^+$ and expressed IL-4 and IL-5, whereas M2-specific or F-glycoprotein-specific T-cell lines were $CD4^+$ or $CD8^+$ and expressed Th1-type cytokines. The relationship of Th1- to Th2-type cytokine expression appears important in the outcome of RSV immunity or disease pathogenesis (Lemanske 1998; Welliver 2000;

Graham et al. 2002). Primary RSV infection induces a mixed Th1- and Th2-type cytokine response with limited disease pathogenesis (Openshaw et al. 2002), and from animal studies, it appears that early IFN-γ expression is key in controlling the Th1/Th2 cytokine balance (Spender et al. 1998; Boelen et al. 2002; Openshaw et al. 2002). Absence of IFN-γ early after primary infection or during subsequent RSV infections has been shown to result in a predominant Th2-type cytokine response and increased disease severity (Hussell et al. 1997; Boelen et al. 2002; Durbin et al. 2002). The relationship between phenotypes associated with cell activation and cytokine expression was investigated in RSV-infected BALB/c mice (Tripp et al. 2000c). In this study, $CD54^+$ and $CD102^+$ lymphocytes expressed higher levels of IL-2, IL-4, IL-5, and IFN-γ compared to $CD44^+$, $CD49d^+$ or $CD62L^{lo}$ lymphocytes, and DNA analysis of lymphocytes expressing IL-2 or IFN-γ revealed higher G2/M levels compared to lymphocytes expressing IL-4 or IL-5, suggesting greater activation of Th1-type lymphocytes in the lungs in response to RSV infection.

IMMUNOPATHOLOGY AND THE RESPONSE TO RSV PROTEINS

Immune-mediated pathology was first indicated in clinical trials of FI-RSV vaccine parentally administered to infants who subsequently developed enhanced pulmonary disease upon natural RSV infection (Chin et al. 1969; Fulginiti et al. 1969; Kapikian et al. 1969; Kim et al. 1969). The vaccine failure is generally attributed to poor protection, and an unbalanced immune response to vaccination (Murphy et al. 1986c). The poor protection may be linked with a weak neutralizing secretory IgA response associated with parental vaccination, or an unbalanced humoral response to vaccination. FI-RSV vaccinees developed high titers of serum antibodies to the F glycoprotein, but these antibodies did not exhibit effective neutralizing activity (Murphy et al. 1986c). In addition, vaccinees had low levels of serum antibodies to the G glycoprotein, suggesting that G glycoprotein immunogenicity was altered by formalin-inactivation. Lung histopathology of FI-RSV vaccinees who died revealed extensive infiltration of neutrophils and eosinophils that is not associated with primary RSV infection in mice (Chin et al. 1969; Graham et al. 1993; Waris et al. 1996). Unfortunately, investigation of the $CD4^+$ and $CD8^+$ T-cell response was not available during this vaccine trial, thus cell-mediated responses to FI-RSV vaccination have been inferred from experimental animal studies.

FI-RSV vaccine studies in experimental animal models, particularly mice and cotton rats, suggest that enhanced pulmonary disease is primarily mediated by $CD4^+$ T cells and Th2-type cytokines, as depletion of $CD4^+$ T cells or IL-4 or IL-10 abrogates enhanced disease (Connors et al. 1992b, 1994). The RSV G glycoprotein appears to sensitize for enhanced disease, skewed Th2-type cytokine and chemokine responses, and to enhance pulmonary expression of substance P, a neurogenic mediator of inflammation (Johnson et al. 1998; Johnson and Graham 1999; Graham et al. 2000; Tripp et al. 1999, 2000a, b, d). G glycoprotein sensitization for enhanced pulmonary disease has been shown to be associated with T-cell epitopes on the G glycoprotein comprising amino acids 185–193 (Srikiatkhachorn et al. 1999), 184–198 (Tebbey et al. 1998), or 193–202 (Sparer et al. 1998); however, the response mediated by the G glycoprotein may not be epitope-specific, since the form and site of administration of G glycoprotein available for antigen processing and presentation has been shown to be an important factor sensitizing for enhanced pulmonary disease (Bembridge et al. 1998). G-glycoprotein-associated Th2-type responses including high IL-4, IL-5, and IL-13 cytokine expression by infiltrating leukocytes, pulmonary eosinophilia, and extensive inflammation upon live RSV challenge (Openshaw 1995a; Graham et al. 2000; Openshaw et al. 2001). The T-cell repertoire is also altered by G-glycoprotein sensitization, characterized by constrained TCR $V\beta14^+$ usage by $CD4^+$ T cells responding to RSV challenge, and in vivo elimination of TCR $V\beta14^+$ cells has been shown to abolish Th2-type pulmonary disease (Varga et al. 2001). A recent study from our laboratory indicates that FI-RSV-enhanced disease is associated with G-glycoprotein expression, and in particular the G-glycoprotein CX3C motif, and that pulmonary substance P expression contributes to the enhanced inflammatory response associated with FI-RSV vaccination (Haynes et al. 2003). Interestingly, G-glycoprotein-specific cytotoxic T-cell responses are not readily detected in humans or mice; however, mice sensitized to G glycoprotein generate Th1 and Th2 $CD4^+$ T-cell responses (Hancock et al. 1996). By contrast, mice sensitized to RSV F glycoprotein induce potent cytotoxic T-cell responses, and Th1 $CD4^+$ T-cell responses (Alwan and Openshaw 1993).

In addition to sensitizing for Th2-type $CD4^+$ T-cell responses and altering the T-cell repertoire, the G glycoprotein has been associated with other immune modulatory features. BALB/c mice infected with wild-type RSV have markedly reduced pulmonary trafficking of neutrophils and NK cells, increased pulmonary substance P expression, and reduced CC and CXC chemokine mRNA expression by bronchoalveolar lavage (BAL) cells compared to mice infected with an RSV mutant lacking *G* and *SH* genes (Tripp et al. 1999, 2000a, 2000d). It is possible that skewed Th2-type $CD4^+$ T-cell responses associated with G glycoprotein expression are affected by reduced CC and CXC chemokine expression. MIPs and inflammatory protein (IP)-10 are chemotactic for cells bearing the chemokine receptors CCR1, CCR5, and CXCR3 (Kabashima et al. 2001; Luther and Cyster 2001; Sauty et al. 2001). These chemokine receptors are preferentially expressed on

Th1 cells (Loetscher et al. 1998; Odum et al. 1999; Syrbe et al. 1999), thus decreased expression of MIP and IP-10 may impair recruitment of Th1-type cells favoring Th2-type cell recruitment. The G glycoprotein can also mimic the activities of the only known CX3C chemokine, fractalkine (Tripp et al. 2001). G glycoprotein contains a CX3C chemokine motif that interacts with the CX3C chemokine receptor, CX3CR1. The structural similarity between the G glycoprotein CX3C motif and the fractalkine CX3C motif is shown in Figure 5. G glycoprotein CX3C with CX3CR1 can compete with fractalkine for binding to CX3CR1, induce leukocyte chemotaxis in a fashion similar to fractalkine, and facilitate virus infection. The results suggest that G glycoprotein interaction with CX3CR1 may be important to the biology of RSV infection and possibly disease pathogenesis.

The form of the G glycoprotein appears to be important in immunity and disease pathogenesis. The secreted form of the G glycoprotein is more potent in inducing pulmonary eosinophilia than the membrane-anchored form (Johnson et al. 1998), and sensitization with the secreted form is associated with increased expression of IL-5, IL-13, and eotaxin (Johnson and Graham 1999). Pulmonary eosinophilia mediated by soluble G-glycoprotein sensitization does not require IL-4 expression, but does require IL-5, and if both IL-4 and IL-13 are inhibited at the time of immunization, the development of pulmonary eosinophilia upon RSV challenge is reduced (Johnson and Graham 1999). By contrast, presentation of RSV F in a soluble form does not sensitize for pulmonary eosinophilia, but does induce IL-4 and IL-5 (Bembridge et al. 1999). RSV-specific $CD8^+$ T cells and IL-12-activated NK cells appear to regulate development of G-glycoprotein-mediated enhanced disease. If RSV-specific $CD8^+$ T cells are present at the time of G-glycoprotein sensitization, the development of pulmonary eosinophilia and enhanced disease is reduced (Alwan et al. 1994; Hussell et al. 1997). Similarly, IL-12-activated NK cells can reduce pulmonary eosinophilia mediated by G-glycoprotein sensitization, but do not enhance the severity of illness in the absence of $CD8^+$ T cells (Hussell and Openshaw 2000).

EPIDEMIOLOGY

Viral respiratory tract infections can be severe during infancy, and viral bronchiolitis is the most common cause of infant and young children hospitalization in the developed world (Leader and Kohlhase 2002; Staat 2002). RSV is the primary cause of lower respiratory tract infections among infants and young children, accounting for approximately 70 percent of all cases of viral bronchiolitis (Glezen et al. 1986). During a 17-year study period in the USA, an estimated 1.65 million hospitalizations for bronchiolitis occurred among children younger than 5 years, and 57 percent of these hospitalizations occurred among children <6 months of age (Shay et al. 1999). RSV activity in the USA monitored by the National Respiratory and Enteric Virus Surveillance System at the Centers for Disease Control and Prevention (CDC) has shown that RSV outbreaks occur between October and April (Figure 1). Examining the number of bronchiolitis hospitalizations in 1994–1996 from November through April in the USA, it is estimated that 51 240–81 985 annual bronchiolitis hospitalizations among children younger than 1 year were related to RSV infection (Shay et al. 1999). In the USA, the risk of primary RSV infection in infants <12 months of age ranges from 50 to 70 percent, and approximately 30–40 percent of children in this age group develop lower respiratory tract illness (Parrott et al. 1973; Glezen et al. 1986). By age 2, most children have experienced at least one RSV infection (CDC 2000), and the risk for lower respiratory tract illness remains high with re-infection, and through the first 5

years of life (Glezen et al. 1986; Wright et al. 1989). The risk of serious RSV infection is high in patients with underlying disorders of the cardiac, pulmonary, or immune system (Wendt 1997; Englund et al. 1999; Falsey and Walsh 2000; Whimbey and Ghosh 2000; Hall 2001; Aujard and Fauroux 2002; Greenberg 2002; Ison and Hayden 2002). Diagnostic studies using RT-PCR indicate that RSV may cause approximately 50 percent of all respiratory tract illness in adult patients. RSV is recognized as a major cause of serious disease in older adults and the elderly, and is associated with high morbidity and some mortality in older persons residing in nursing homes and in the community (Falsey 1998; Han et al. 1999). The relationship of serum antibody to RSV and risk of RSV infection suggests that older adults with low titers of serum neutralizing antibody may be at greater risk of developing symptomatic RSV infection than those who have high antibody titers (Falsey and Walsh 1998). Applying rates of RSV detection from prospective studies of lower respiratory tract illness in adults to national hospital discharge diagnosis and death certificate data, it is estimated that RSV causes 14 000–62 000 hospitalizations and 1 500–6 700 deaths each year in the USA in older adults and the elderly (Han et al. 1999). The impact of RSV strain variation on the epidemiology of RSV disease is not completely understood; however, RSV outbreaks appear to be community-based. The circulation patterns of RSV A and B strains appear genotypically distinct among communities with limited diversity between strains of the same genotype, but greater diversity in genotype in strains from different communities (Peret et al. 1998, 2000). Isolates of RSV strain A appear to be more common than strain B, and individual outbreaks of RSV infection may differ substantially in strain predominance; however, no substantial linkage has been made between strain variation, hospitalization, and disease severity. RSV is a major cause of nosocomial infections (Hall 1983), particularly for premature infants and the immune compromised (CDC 2002; Hall 2000; Jones et al. 2000; Heerens et al. 2002).

Nosocomial pneumonia is a common hospital-acquired infection in children, and is often fatal. Viruses, predominantly RSV, are the most common cause of pediatric nosocomial respiratory tract infections (Hall 1983; Mlinaric-Galinovic and Varda-Brkic 2000). Risk factors for nosocomial pneumonia include hospitalization during the RSV season, age, underlying chronic disease, admission to an intensive care unit, intubation, burns, surgery, immune suppression, and long hospitalization. The morbidity and cost associated with nosocomial RSV infection of infants is striking (Macartney et al. 2000). About 40 percent of nosocomial RSV infections are associated with lower respiratory tract disease in this young age group (Hall 1983). RSV appears to be nosocomially transmitted by fomites on the hands of hospital personnel (Hall et al. 1980). Medical staff infected with community-acquired or nosocomially acquired RSV are frequently unaware of RSV infection because infection may present as mild flulike illnesses. However, RSV infection may debilitate up to 40 percent of those infected, resulting in absence from work (Hall et al. 1978). The key to control of nosocomial transmission of RSV is compliance with guidelines for prevention and surveillance described by the CDC. Education of hospital personnel about the nature of RSV, active surveillance among patients, careful hand washing, and use of gloves and barriers are important in controlling infection (Snydman et al. 1988; Madge et al. 1992; Goldmann 2001); however, prevention through the use of masks and gowns has not been successful (Hall and Douglas 1981; Murphy et al. 1981).

The disease burden of hMPV is not well known. Recent identification of hMPV in the Netherlands was made from respiratory samples submitted for viral culture during the winter season associated with RSV infection (van den Hoogen et al. 2001). Approximately half the initial 28 samples were cultured from infants <1 year of age, and 96 percent were isolated from children <6 years of age. Seroprevalance studies of children aged 6–12 months indicated that approximately 25 percent had detectable antibodies to hMPV, and by age 5 all patients showed evidence of past exposure or infection. In Australia, three of 200 randomly chosen respiratory samples negative for known respiratory pathogens, were positive for hMPV on culture, RT-PCR, or both (Howe 2002). From Canada, 11 isolates from 10 patients aged 2 months to 87 years of age with acute respiratory tract illness during the winter season were identified as hMPV at the CDC (Peret et al. 2002). Two major groups or strains of hMPV were identified in Canadian isolates based upon sequence diversity. Similar to RSV, some of the hMPV isolates did not originate from a single outbreak, but were from unrelated cases of respiratory illness. The serological studies of hMPV infection in the Netherlands, and epidemiological features associated with studies at the CDC and in Australia, suggest that hMPV likely infects most children by age 5, co-circulates with RSV, and may cause repeated infections.

PERSPECTIVE

RSV disease remains a major public health problem, and limited prophylactic or therapeutic treatments are available. Significant progress is being made toward understanding the virus–host relationship related to immunity and disease pathogenesis, and these studies have led to several promising RSV vaccine candidates that are under clinical evaluation. The development of a safe and efficacious RSV vaccine remains a challenging task, as does preventing infection or controlling RSV infection in infants, the elderly, or immune-compromised patients. Success in these areas will likely require

different vaccine and treatment strategies. Our limited understandings of durable immunity to RSV, immune-modulating activities of viral proteins, enhanced disease mechanisms associated with formalin-inactivated RSV vaccines and mechanisms that contribute to immunity or disease complicate vaccine development. Development of successful prophylactic or therapeutic treatments to reduce virus load and inhibit inflammation remains a priority. Progress towards these goals is occurring through experimental animal studies; however, more rapid translation of the findings to humans is required. The discovery of hMPV and its clinical relationship to RSV emphasizes the need for a better understanding of the disease burden associated with hMPV infection, the relationship between RSV and hMPV immunity, and the associated disease pathogenesis.

Paramyxoviruses of animals

PAUL A. ROTA AND THOMAS BARRETT

Morbilliviruses	1	Rubulaviruses	12
Avulaviruses (Newcastle disease virus)	9	Unassigned paramyxoviruses	13
Henipaviruses	10	References	13

This chapter describes the clinical and pathological aspects of infections caused by viruses of the family *Paramyxoviridae*, subfamily *Paramyxovirinae* that occur in birds and mammals (Figure 1). The emphasis is on viruses that are important veterinary pathogens, as well as those that also cause severe disease when transmitted to humans.

MORBILLIVIRUSES

Within the family *Paramyxoviridae*, members of an antigenically closely related group of viruses, the genus *Morbillivirus* (Figure 2) are responsible for some of the most devastating viral diseases in domestic and wild animal populations (Barrett 2001). Generally each virus species causes severe clinical signs in only one order of mammals, but the full host range in terms of infection is unknown. They share many clinical and pathological characteristics; in particular they are all highly immunosuppressive (Heaney et al. 2002). Despite this, animals which recover from an infection develop strong cellular and humoral immune responses, which give subsequent life-long protection, and can also give cross-protection against infection with other morbilliviruses.

Rinderpest

Rinderpest, also known as cattle plague, can infect a variety of cloven hoofed animals, for example cattle, buffalo, yak, and antelope, where it generally causes an acute febrile illness 3–15 days after infection. The term 'cattle plague' is now usually used to denote a severe outbreak of this disease in nonendemic areas, whereas 'rinderpest' is the term used most often in endemic regions. The last outbreak of classical cattle plague with very high mortality and economic losses occurred in Pakistan in 1994–1995 (Rossiter et al. 1998). In its most severe form it has been characterized as the disease of the three Ds: discharge, diarrhea, and death. Historically, rinderpest has been a major problem in Europe and Asia, but it was eliminated from Europe by the beginning of the twentieth century using zoosanitary control measures. Sporadic introductions, which were quickly contained, occurred in Europe, the Americas, and Australia in the early twentieth century. This led to the establishment of the Office International des Epizooties (OIE), an international veterinary organization which acts as a World Health Organization for animal diseases. As the disease was being eliminated from Europe it was introduced into Africa in about 1887 and caused a major pandemic on that continent killing over 90 percent of the cattle and buffalo, resulting in great social and economic hardship (Barrett and Rossiter 1999; Mack 1970).

CLINICAL AND PATHOLOGICAL MANIFESTATIONS

Virus enters by the respiratory route and replicates in the draining lymph nodes of the head and throat. White blood cells, lymphoblasts, and macrophages become infected and the virus spreads via the blood and lymph to other lymphatic tissues, and then to the lungs, mucous membranes, and gastrointestinal tract. Virus excretion begins 24–48 h before the onset of clinical signs and lasts for 7–10 days. Typically, the animal develops nasal and ocular congestion, which progresses to give profuse lacrimal and nasal discharges which can become mucopurulent. Necrotic lesions appear on all mucous

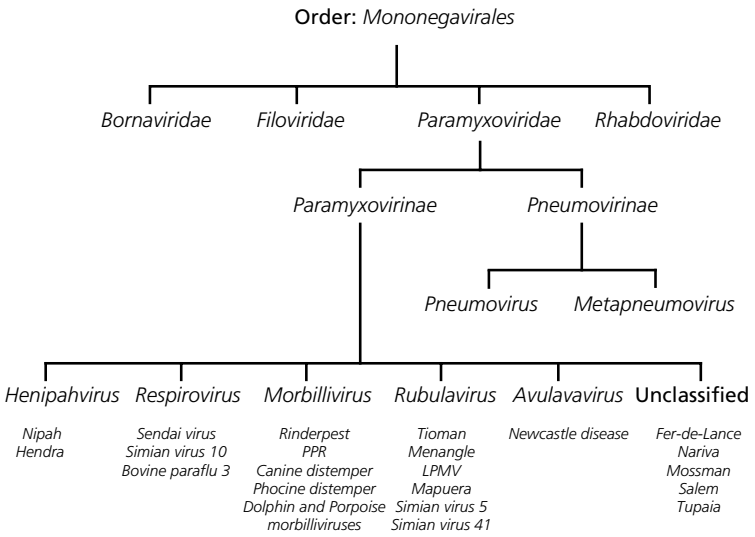

Figure 1 *Classification of the viruses within the order* Mononegavirales. *Family* Paramyxoviridae *is divided into two subfamilies, and there are five genera within the subfamily* Paramyxovirinae.

membranes, especially in the mouth where the lips, gums, buccal papillae, and tongue can be affected. Lesions on the mucous membranes and in the gastrointestinal tract are responsible for the severe manifestations of the disease. The animals become depressed, anorexic, and emaciated because the mouth lesions make eating painful. The intestinal pain causes them to arch their backs and the hair becomes rough and soiled by the mucopurulent discharge and watery, often bloody, diarrhea. Severe diarrhea results in dehydration and the animals have sunken eyes and reduced skin turgor. Pregnant animals usually abort and recovery is prolonged in survivors, but results in life-long protection from disease. Pathological findings include severe lymphodepletion, necrosis of the Peyer's patches and lesions in many parts of the digestive tract. The blood becomes concentrated and slow to circulate and the blood vessels in the longitudinal folds of the large intestine become distended and appear prominent, giving a marked striped appearance, the so-called zebra stripes. The lungs are generally minimally affected in rinderpest infections. Mortality can be as high as 70–90 percent in such severe cases, but there is considerable variation in the severity of symptoms, and even asymptomatic infections can occur, depending on the virulence of the virus strain involved and the host's innate resistance. Cattle of *Bos indicus* species are more resistant than *Bos taurus* species (Scott 1990). In endemic areas, mortalities of

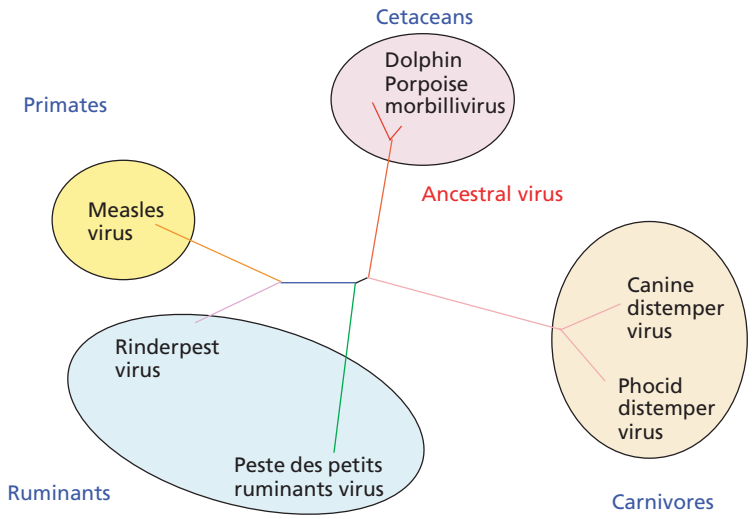

Figure 2 *Phylogenetic tree showing the relationships between the different morbilliviruses based on partial sequence of the* P *gene. A universal primer set was used to amplify a 429-base pair DNA fragment as described by Barrett et al. (1993). The tree was derived using the PHYLIP DNADIST and FITCH programmes (Felsenstein 1997). The branch lengths are proportional to the mutational differences between the viruses and the hypothetical common ancestor that existed at the nodes in the tree.*

30 percent, or less, are more normal. The pathogenesis of rinderpest infection has been extensively described (Brown and Torres 1994; Wamwayi et al. 1995; Wohlsein et al. 1993, 1995). The disease follows a similar course in wildlife species, except that skin lesions and corneal opacity are often seen, especially in buffalo and kudu, and this greatly increases the risk of predation (Kock et al. 1999).

EPIZOOTIOLOGY

The virus is present in all secretions and excretions from the infected animal but, since the virus is labile, it requires close contact for infection to occur, most often by infected air droplets. Contaminated fomites can also be a source of infection but nearly all outbreaks can be traced to the introduction of unvaccinated stock infected with the virus (Wamwayi et al. 1992; Rossiter 2001a; Rossiter et al. 1998). In endemic areas, rinderpest disease is most often seen in animals less than 2 years of age, as older animals are generally immune due to previous exposure. Maternal immunity protects the very young for up to 6 months. Until the mid-1990s, rinderpest was endemic in many parts of southern Asia, the Middle East, and Africa (Rweyemamu and Cheneau 1995); however, the intense vaccination campaigns carried out over the past decade have reduced the endemic region to a small area of eastern Africa on the borders of Somalia and Kenya. There are three distinct lineages of the virus, two African and a third found exclusively in Asia (Barrett et al., 1998) (Figure 3). The virus remaining in this last endemic focus is of African lineage 2 and appears to be maintained in cattle as a mild infection, but it becomes clinically apparent when it spreads, by means of trade and cattle movement, to areas where there are susceptible wildlife species such as buffalo, eland, and kudu (Kock et al. 1999). It has been suggested that rinderpest is the archetypal morbillivirus and it is likely that other morbilliviruses evolved form a ruminant virus of this type (Norrby et al. 1985).

CONTROL

All morbilliviruses are very sensitive to inactivation by heat, ultraviolet (UV) light, and chemicals, especially ones that disrupt the lipid envelope, so zoosanitary measures are very effective in controlling these infections. There is no effective treatment for rinderpest, but infection can easily be prevented by vaccination using a tissue culture attenuated vaccine developed by Plowright and Ferris (1962). There is only one serotype of rinderpest virus, as is the case for other morbillivirus species, and the attenuated vaccine is safe and gives life-long protection with a single shot. The main disadvantage of the vaccine is the inability to distinguish the vaccinated from naturally infected and recovered animals in serological assays. This would be a very useful characteristic to have at this final stage in the global eradication campaign and research is in progress to develop marker vaccines (Walsh et al. 2000).

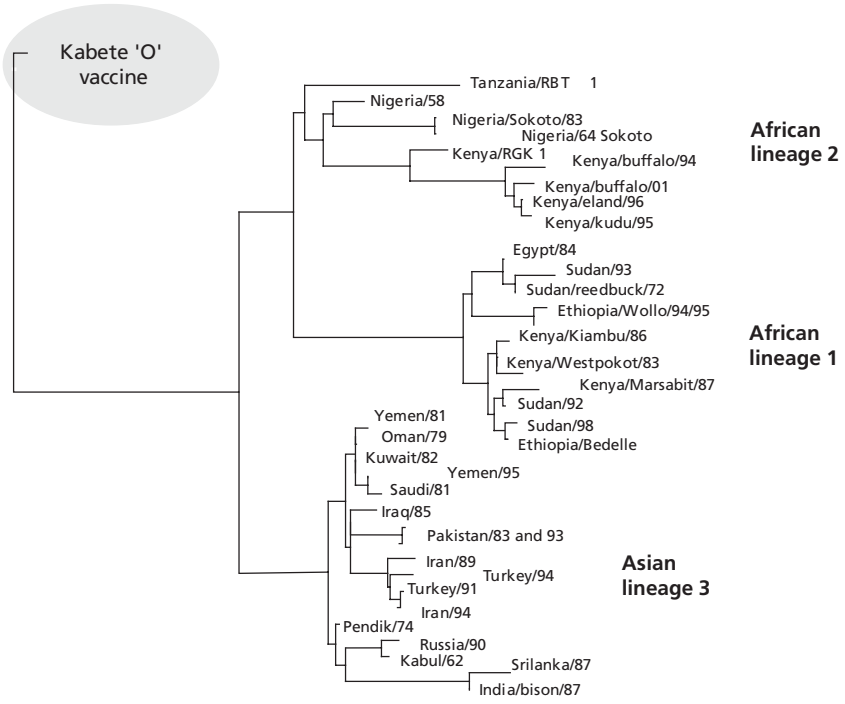

Figure 3 *The relationships between the different rinderpest viruses based on partial sequence data derived from the various fusion protein genes. A specific primer set was used to amplify a 372-base pair DNA fragment as described by Forsyth and Barrett (1995). The tree was derived as described in Figure 2.*

In nonendemic areas, a quarantine and slaughter policy has proved the most effective means of control. However, in endemic regions, or where cultural considerations prohibit slaughter, mass vaccination accompanied by restriction of animal movement and market closures are the control measures used. Because of the severe economic losses incurred as a result of rinderpest in Africa and Asia in the 1980s, a concerted international control and vaccination program was set up. This is now known as the Global Rinderpest Eradication Programme (GREP) with a target of eradication by 2010.

LABORATORY DIAGNOSIS

Rapid and accurate diagnosis of rinderpest has important implications for disease control programs as the clinical signs can be confused with those of other less serious diseases, such as bovine viral diarrhea and malignant catarrhal fever viruses. Classic cattle plague can be diagnosed clinically in nonendemic areas relatively easily but mild rinderpest, or disease in vaccinated populations, can only be diagnosed with certainty by laboratory testing. The virus can be detected by isolation in tissue culture cells (either primary bovine kidney cells or B95a cells), by antigen detection using various assays, for example agarose gel immunodiffusion, counter-immunoelectrophoresis, or preferably immunocapture enzyme-linked immunosorbent assay (ELISA) (Anderson et al. 1996; Libeau et al. 1994). A pen-side test, based on the use of virus-specific monoclonal antibodies, has been developed to detect virus antigen in samples taken in the field and this has greatly helped veterinarians investigating a potential outbreak to diagnose the disease and differentiate it from others with similar clinical manifestations (Wambura et al. 2000). Recently, reverse transcription polymerase chain reaction (RT-PCR) has been the method of choice for laboratory diagnosis as the resulting PCR product can be sequenced to give valuable information on the strain of virus involved (Forsyth and Barrett 1995; Barrett et al. 1998). Antibody responses can be detected in surviving animals, or following vaccination, by virus neutralization assays; however, for the large numbers of sera that are required to be tested for control programs a competitive ELISA has been developed which has proved highly robust and is routinely used in laboratories in countries where the virus remains a threat (Anderson and McKay 1994; Anderson et al. 1996). This assay is also being used for serosurveillance purposes to ensure that countries are free, and remain free, of disease.

Peste des petits ruminants virus

Peste des petits ruminants (PPR) is a disease mainly of sheep and goats, which is clinically very similar to rinderpest in large ruminants. Where it occurs it is considered to be one of the most economically important diseases in these species. Generally goats are more sensitive to PPR than sheep, but that can be strain-dependent. The disease was first seen in West Africa in the 1940s (Gargadennec and Lalanne 1942), but is now known to be widely distributed in sub-Saharan Africa. In the 1990s the Arabian peninsula, the Middle East, and most parts of the Indian subcontinent were swept by an epizootic of PPR where it has remained (Dhar et al. 2002; Ozkul et al. 2002).

CLINICAL AND PATHOLOGICAL MANIFESTATIONS

Like rinderpest, peste des petits ruminants virus (PPRV) infection is characterized by high fever, ocular and nasal discharges, necrosis in the mouth, and inflammation of the gastrointestinal tract leading to diarrhea and dehydration (Rossiter 2001b). However, unlike rinderpest in cattle, interstitial and suppurative pneumonia is commonly found in PPRV-infected animals and secondary bacterial infections (usually *Pasteurella* spp.) are often a complicating factor and so it can be easily confused with contagious caprine pleuropneumonia (CCPP). The pathological findings are very similar to those described for rinderpest infections, apart from the more marked lung involvement and severe bronchopneumonia. Giant cells are seen in the bronchioles and terminal alveoli, usually with intracytoplasmic and intranuclear inclusion bodies (Rossiter 2001b). Mortality rates in PPR epizootics can range from 10 to 90 percent and may vary with the host's innate resistance, body condition, age, complications resulting from secondary bacterial and parasitic infections, and perhaps, the virulence of the virus involved (Kitching 1988). However, little research has been carried out to establish these as facts.

EPIZOOTIOLOGY

The virus circulates in endemic areas in sheep and goats, but the full host range of this virus is unknown. There is no indirect transmission of the virus and no known wildlife reservoir; however, captive wildlife are known to be highly susceptible. Several species of wild antelope died as a result of infection in a zoo in the United Arab Emirates (Furley et al. 1987) and recently an epizootic killed many gazelle in a game park in Saudi Arabia (Abu Elzein et al. 2004). In West Africa, PPR is more prevalent in the more humid areas and shows a seasonal pattern. In the Middle East, the intensive trading of small ruminants for religious festivals spreads the virus. Due to the clinical and morphologic similarities of rinderpest and PPR, there was considerable confusion regarding which virus was circulating in large and small ruminants, especially in Asia, as these strains of rinderpest were known to infect sheep and goats and result in clinical disease. PPRV infection has been reported in buffalo in India and in cattle in West Africa (Anderson

and McKay 1994; Govindarajan et al. 1997). This can interfere with the take of the rinderpest vaccine and cause confusion in serological surveillance; however, if the GREP is successful, this will no longer be an issue. PPRV isolates have been grouped into four distinct lineages on the basis of fusion (F) protein gene sequence similarities and they reflect the geographical distribution of virus strains (Shaila et al. 1996; Dhar et al. 2002) (Figure 4).

CONTROL

Zoosanitary measures, as applied to rinderpest control, are effective but often difficult to implement because of the large numbers of animals involved and the nomadic nature of many small ruminant pastoralists. These are often amongst the poorest members of society and depend very heavily on small ruminants for economic survival. Vaccination of herds is the most effective means of controlling PPR and at first, because of the close antigenic relatedness, the rinderpest vaccine was used to protect animals against PPR, but a homologous vaccine has now been developed and is widely used to control the disease (Couacy-Hymann et al. 1995). In endemic areas, captive wild animals should be kept well separated from local sheep and goat flocks, as the safety of the PPR vaccine in wild species has not yet been established.

LABORATORY DIAGNOSIS

The virus can be isolated most easily in primary sheep or goat kidney or skin cell cultures and it can also be grown after several blind passages in Vero cells. Laboratory techniques for detecting the virus have developed in parallel with those for rinderpest because of the need for differential diagnosis of the two infections and specific antibody, antigen and RNA detection tests are now available to distinguish the two viruses (Forsyth and Barrett 1995; Anderson et al. 1996; Libeau et al. 1994).

Canine distemper virus

Canine distemper virus infects a variety of carnivores, most notably the dog, mink, and ferret among domestic species. The epizootiology in wild carnivores is poorly understood but infections in these species have been more extensively studied in recent years.

CLINICAL AND PATHOLOGICAL MANIFESTATIONS

Disease is most often seen in young animals, but can also occur in older animals. Infection begins in the upper respiratory tract and, after an incubation period which can range from 1 to 6 weeks, spreads in a similar fashion to other morbilliviruses, that is from the local lymph nodes via the lymph and blood to other lymphatic

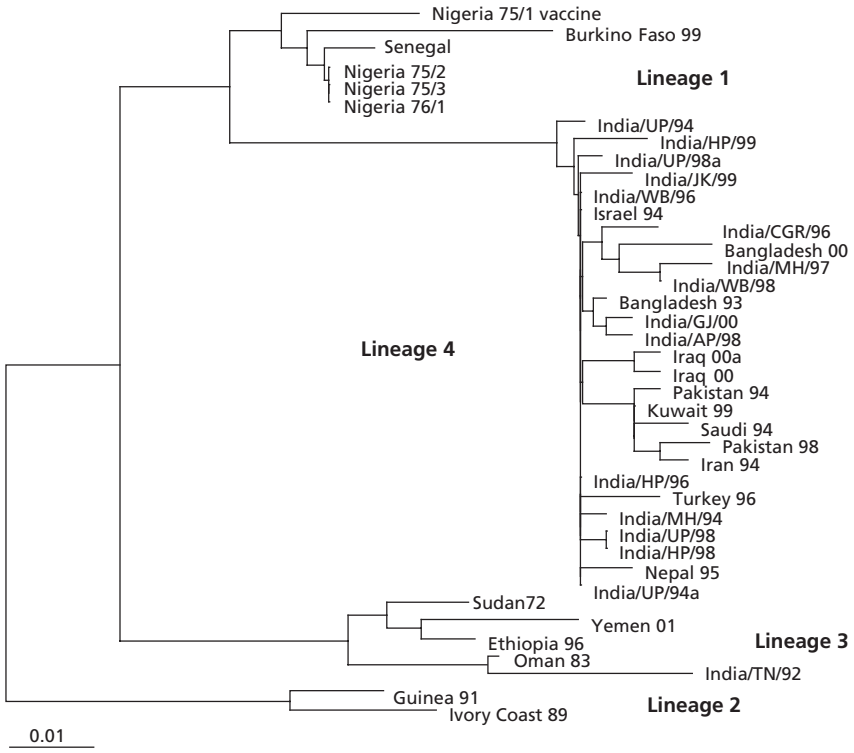

Figure 4 *The relationships between the different peste des petits ruminants viruses based on partial sequence data derived from the fusion protein gene. A specific primer set was used to amplify a 372-base pair DNA fragment as described by Forsyth and Barrett (1995). The tree was derived as described in Figure 2.*

tissues and then to the upper and lower respiratory tracts, gastrointestinal mucosa, and brain. Following an initial febrile response, infected animals suffer depression and develop mucopurulent nasal and ocular discharges, vomiting, diarrhea, and pneumonia, signs commonly seen in other morbillivirus infections. A dry cough may develop which progresses to a moist cough. However, the most striking difference between canine distemper and the ruminant morbilliviruses is the virus' ability to infect neurons and other cells of the nervous system, but the neurotropism of isolates can also vary considerably (Stettler et al. 1997). Brain infection results in a nonsuppurative encephalitis, meningoencephalitis, neuronal necrosis, and demyelination. Neurological signs such as seizures, tremors, disorientation, incoordination, coma, or behavioral changes are often present and can develop acutely weeks or months later. Another aspect of the disease that differs from that caused by rinderpest and PPR infections is a hyperkeratosis that commonly develops on the foot pads (so-called 'hard pad'). There can be considerable variation in the severity of disease and this is partly related to differences in the infecting strain, often referred to as a biotype, and the individual and species involved (Appel 1987). A strong humoral antibody response to the virus may result in mild or inapparent disease and the virus is cleared quickly but if a weak response is mounted, and the animal recovers from the inevitable disease, it can shed virus for 2 to 3 months. While early development of circulating antibody has been shown to be crucial for protection and recovery from canine distemper infections that is not the case for the ruminant morbilliviruses where a cell-mediated response appears to be more important for protection.

EPIZOOTIOLOGY

Canine distemper is found worldwide, with the exception of hot arid regions, and results in periodic disease outbreaks, mostly seen in domestic dogs, but a variety of wildlife species are highly susceptible. For example, disease has been observed in several species of large cat in American zoos, lions and hyenas in the Serengeti plains in Africa, javelinas in Arizona, ferrets, mink, raccoons, coyotes, badgers, foxes, bears, pandas, and seals (Appel 1987; Appel and Summers 1995; Haas et al. 1996; Harder et al. 1996; Roelke-Parker et al. 1996). A retrospective study of pathological specimens from large cats that died of unknown causes in a Swiss zoo indicated that canine distemper was not a new infection in these species (Myers et al. 1997). Ferrets are particularly susceptible to distemper infections and the virus has threatened the survival of the black-footed ferret, a highly endangered species in the USA (Carpenter et al. 1976). Virus is usually maintained in dog populations by transmission to susceptible young via respiratory, ocular, and nasal secretions, which contain the virus. Like all morbilliviruses, it is highly contagious but requires close contact for transmission. In enzootic areas, the density of the susceptible population is an important factor in maintenance and spread and disease is most often seen in young animals after the maternal antibody has waned. In isolated populations, as for other morbilliviruses, epizootics occur which can be severe and affect all age groups (Leighton et al. 1988).

CONTROL

Modified live virus vaccines, the Onderstepoort and Rockborn strains developed in the 1950s, have been very successful in controlling disease in domestic dogs and mink. Maternal antibody decreases the effectiveness of the vaccine, so vaccine should be given after maternal antibody begins to wane at 6–9 weeks of age (Chapuis 1995). Most vaccination protocols recommend giving a second dose at 12–15 weeks of age to ensure an effective vaccination. Live virus vaccines have also been used in nondomestic species, but this is risky and they should only be used if proven safe in that species. Vaccine-induced immunosuppression can be a problem in animals such as the panda (Bush et al. 1976; Deem et al. 2000). Threatened and endangered wild carnivores are best protected by ensuring good vaccination cover in domestic dogs living near wildlife reservations and minimizing contact. Domestic dogs were considered the most likely source of the virus that infected the lions, hyenas, and wild dogs in Africa (Roelke-Parker et al. 1996).

LABORATORY DIAGNOSIS

The virus can be isolated in cell culture or virus-specific antigens and RNA can be detected in infected secretions, blood, and affected tissues. Vero and dog kidney cells have been used for virus isolation, although not all strains grow well in these culture systems. Pulmonary alveolar macrophages and mitogen-stimulated canine or ferret blood lymphocytes are the most sensitive cell culture system for canine distemper virus (Appel et al. 1992). Viral antigens can be detected by immunofluorescence in conjunctival smears or by immunohistochemistry carried out on fixed tissues. Viral RNA can be detected by RT-PCR assays using specific primer sets (Forsyth and Barrett 1995; Kennedy et al. 2000). The most important differential diagnosis is for rabies virus because of the implications for human health.

Morbillivirus infections of aquatic mammals

Morbillivirus infections in marine mammals were unknown before 1987, but since then several newly recognized members of the genus *Morbillivirus* have been identified as the etiological agent of disease and mortality in the orders *Pinnipedia* (seals) and *Cetacea* (whales, porpoises, and dolphins). The first to be recog-

nized was phocine (seal) distemper virus, which had severe ecological consequences for the European harbor seal (*Phoca vitulina*). Thousands of this species died along the coasts of northern Europe in 1988 (Osterhaus and Vedder 1988). The virus was also identified in European gray seals (*Halichoerus grypus*), but they have proved to be more resistant to the virus. Subsequently two other morbilliviruses were isolated from marine mammals, namely the dolphin and porpoise morbilliviruses (Barrett and Rima 2002; Kennedy et al. 1988; Domingo et al. 1990). The genetic similarity of the dolphin and porpoise viruses would indicate that they are variations of the same virus and they are collectively referred to as the cetacean morbillivirus (Barrett et al. 1993). Canine distemper virus has also been shown to infect and kill several species of seal (Kennedy et al. 2000; Grachev et al. 1989; Mamaev et al. 1995).

CLINICAL MANIFESTATIONS

Seals infected with either phocine distemper virus or canine distemper virus show a loss of body condition (reduced blubber thickness) along with the normal signs of a morbillivirus infection, fever, serous or mucopurulent oculonasal discharge, conjunctivitis, dyspnea, diarrhea, lethargy nervous signs, and abortion in pregnant females. Pneumonia was the main gross pathological finding in seals with the airways containing mucopurulent, blood-stained, or frothy exudates. Central nervous system (CNS) degeneration was also observed. Clinical data for infected cetaceans are less comprehensive as sick animals have not been observed under confined conditions and no experimental infections have been carried out. During the epizootic in the Mediterranean in 1990–1991, many striped dolphins (*Stenella coeruleoalba*) were found to be in poor body condition and loss of fat stores led to decreased buoyancy. Skin lesions and necrosis of the buccal mucosa, lymphodepletion, and hemoconcentration were commonly observed. Other clinical signs in striped dolphins included tachycardia, abnormal respiratory rates, lethargy, and reduced sound emissions. Bronchopneumonia was the most marked pathological feature in dolphins, along with CNS degeneration. The majority of the sick seals and dolphins had nonsuppurative encephalitis, some with signs of demyelination, which explained their behavioral changes (Domingo et al. 1992; Duignan et al. 1992).

EPIZOOTIOLOGY

Phocine distemper virus

The small size and scattered nature of European seal populations means it is unlikely that they could maintain this virus in circulation and indeed the virus disappeared from these populations following the epizootic in 1988. In 2002, another outbreak, following an almost identical course, occurred. Infection most probably results when interspecies transmission introduces or reintroduces the virus to a susceptible population. The similarities in the course of the two European outbreaks may be explained by the migratory and breeding habits of the seals and there is a growing consensus among some seal biologists that gray seals may be key vectors in the transmission of phocine distemper between harbor seal colonies in European waters. This is especially so where large geographical jumps are made. Harbor seals usually return to the same haulout, whereas gray seals do not and move much greater distances between these sites. Another factor may be the relative resistance of this species to the virus enabling it to transmit without necessarily showing severe clinical disease. Since it is likely that most virus transmission occurs on land, their mixing at shared haulout sites most probably explains the timing in early summer to autumn. More than 20 000 seals died during each of the two European phocine distemper outbreaks. The original source of virus in the 1988 and 2002 outbreaks was probably Arctic harp seals (*Phoca groenlandica*), which came into contact with northern European gray seals (Dietz et al. 1989). Serological evidence suggests that the disease is endemic in many species of Arctic seals and has affected Atlantic walruses (*Odobenus rosmarus*), but the full host range and clinical disease induced in most species has not been fully determined (Duignan et al. 1997; Nielsen et al. 2000). Phocine distemper virus can also threaten terrestrial mammals and during the 1988 epizootic in Europe the virus clinically infected farmed mink in Denmark (Blixenkrone-Møller et al. 1990) and there is evidence for phocine distemper and dolphin distemper virus antibodies in Canadian terrestrial carnivores (Philippa et al. 2004).

As mentioned above, phocine distemper is not the only morbillivirus known to cause disease in seals and canine distemper virus infection can also result in significant mortality in these species. Immediately prior to the European seal epizootic, during the winter of 1987–1988, Lake Baikal seals (*Phoca sibirica*) suffered an unusual and severe mortality and there was no possible epidemiological connection between the two events (Grachev et al. 1989). Subsequently canine distemper virus, rather than phocine distemper virus, was shown to have been the etiological agent in the outbreak (Mamaev et al. 1995). Similarly, mass die-offs occurred in Caspian Sea seals (*Phoca caspica*) in 1997 and 2000, which were also attributed to canine distemper virus (Forsyth et al. 1998; Kennedy et al. 2000). Although not proven, the source of the virus is likely to have terrestrial carnivores, such as wolves, which prey on seal pups. Canine distemper virus has also been implicated in the deaths of thousands of crabeater seals (*Lobodon carcinophagus*) in the Antarctic in the 1950s. Since there are no terrestrial carnivores in the Antarctic, it is thought likely that sledge dogs used at that time were the source of the virus, or possibly the animals were infected by contact with carnivores in New Zealand or South America

during migrations. A subsequent serological survey of Antarctic seals showed them to have a high prevalence of canine distemper-specific antibodies (Bengtson et al. 1991). All morbillivirus infections in seals are clinically similar and so differential diagnosis has to be made, which is most easily done by RT-PCR using universal morbillivirus primer sets and primer sets specific for each virus species (Mamaev et al. 1995; Kennedy et al. 2000).

Cetacean morbillivirus

Cetacean species in all the major oceans of the world have been reported to be seropositive for this virus (Duignan et al. 1996; Van Bressem et al. 2001). The pilot whale (*Globicephala* spp.) appears to be the reservoir and vector for transmission of the cetacean morbillivirus to other species. They move in large groups, known as pods, over great ocean distances and have a worldwide distribution. Over 90 percent of pilot whales involved in mass strandings between 1982 and 1993 were morbillivirus seropositive (Duignan et al. 1995a, b). Although the first report of a cetacean morbillivirus was in 1988 in a porpoise caught off the coast of Northern Ireland (Kennedy et al. 1988), subsequently it was shown that a mass die-off of Atlantic bottlenose dolphins (*Tursiops truncatus*) that occurred along the Atlantic coast of the USA in 1987–1988 was probably the result of morbillivirus infection since more than 50 percent of the animals were found to be morbillivirus positive (Lipscomb et al. 1994). Originally the mortality was thought to have been due to brevitoxins produced by red tides of dinoflagellates. Another epizootic occurred in the Gulf of Mexico in 1993–1994 (Lipscomb et al. 1994). There is also serological evidence of exposure of Florida manatees (order *Sirenia*) to morbillivirus infection but no reports of disease or unusual mortality in this species have been reported (Duignan et al. 1995c).

Some evidence also links the cetacean morbillivirus with seal mortality, although not on the same massive scale seen with phocine or canine distemper viruses. A minor outbreak of disease in seals occurred 1998 along the Belgian and northern French coasts and morbillivirus antigen and nucleic acid were detected in tissues from sick animals which were genetically closely related to either the cetacean morbillivirus or canine distemper virus (Jauniaux et al. 1998). The rare monk seal population of the eastern Mediterranean was not severely affected during an epizootic of this virus which killed thousands of striped dolphins in these waters in 1990–1991; however, the cetacean morbillivirus was found in carcasses of monk seals that died in large numbers off the coast of Mauritania in 1997 (Van de Bildt et al. 2000). At the time, an algal bloom was also considered to be an exacerbating or primary factor, which may have contributed to the very high mortality among adult seals at that time (Harwood 1998).

The long-term effects on marine mammal populations infected with morbilliviruses is not clear and will depend on whether the species concerned is already at dangerously low numbers, for example the Mediterranean monk seals and the Caspian Sea seals (Kennedy et al. 2000; Osterhaus et al. 1992). The catastrophic die-off in one of the few remaining colonies of monk seals off the Mauritanean coast in 1997 wiped out an estimated 70 percent of the population within the space of 1 month, a figure representing about one-third of the total world population, leaving only a few hundred remaining (Harwood 1998). However, in populations with healthier numbers, the situation is not so serious and following the 1988 epizootic the European seal populations recovered their normal levels within a few years.

CONTROL

Control of wildlife diseases is extremely difficult and vaccination poses great logistical problems. One exception has been the success in controlling rabies in wildlife using the vaccinia virus recombinant vaccine, but this required very long and careful development (Pastoret and Brochier 1996). Similar attempts at vaccinating seals with a vaccinia recombinant expressing the canine distemper virus fusion (F) protein failed as the virus did not replicate and elicit an immune response (Van Bressem et al. 1991). Vaccination of wildlife also raises ethical questions concerning the effects of the disturbance such an intervention would have on the population and whether there would be uncontrolled spread of the vaccine in the environment. Protection of vulnerable animals in marine wildlife parks and seal sanctuaries would be acceptable as the animals could be confined until the excretion of any vaccine virus had ceased. In any event, there is no currently licensed vaccine for use in these species. Because of the close antigenic relationship between morbilliviruses, strong cross-protection to infection is given by vaccines for other morbilliviruses. An experimental CDV-ISCOM vaccine has been shown to protect seals from PDV, but the duration of the immunity induced remains uncertain (Visser et al. 1992). Canine distemper vaccines have not been fully tested for safety in seals and these vaccines have been shown to cause death in other wildlife species (Bush et al. 1976; Carpenter et al. 1976; Sutherland-Smith et al. 1997); however, a small trial of live attenuated canine distemper vaccine in seals was successfully carried out in England during the 2002 phocine distemper outbreak. The consensus at present is that wildlife is best protected by vaccination to control diseases in domestic species, for example vaccination of cattle has proved an effective means of eliminating rinderpest from wildlife in Africa, but this is not an option for protecting marine mammals from morbillivirus infection since the marine morbilliviruses are rarely found in terrestrial mammals. Because of the threat posed by canine distemper to

seals, it is recommended that unvaccinated dogs should not be allowed to mix with seals and sledge dogs are no longer used in the Antarctic.

AVULAVIRUSES (NEWCASTLE DISEASE VIRUS)

Newcastle disease virus (NDV) is responsible for outbreaks of severe disease among poultry throughout the world. Since outbreaks reported to the OIE result in severe trade limitations, this disease has serious economic consequences. NDV, also called fowl pest or avian paramyxovirus type 1 (APMV-1), is a member of the subfamily *Paramyxovirinae*. Recently, avian paramyxoviruses have been designated as a new genus, *Avulavirus* (Chang et al. 2001). The genomes of several rubulaviruses, except NDV, contain a small hydrophobic (SH) protein gene that is also not present among the respiroviruses (Lamb and Kolakofsky 2001). Interestingly, the avian paramyxovirus-6 (APMV6) genome was reported to contain a putative SH protein gene (Chang et al. 2001).

Clinical manifestations of infection

NDV causes epidemic disease in a wide range of domesticated and wild birds, most notably among poultry (Alexander 1995). It has been isolated from all orders of birds. The incubation period averages 5–6 days, with a range of 2–15 days. The type and severity of disease varies with the infecting virus strain, as well as the age and species of the infected bird. For example, younger chickens are subject to more severe disease than older chickens. Although there is a continuum of clinical presentations, isolates have been separated arbitrarily into four groups based on the presence of enteric or neural disease and the speed with which they kill embryonating hens' eggs. All strains reduce egg production in chickens.

NDV strains are divided into three pathotypes based on disease severity (Alexander 1997). Lentogenic strains are associated with no, or mild, respiratory tract symptoms and some have been developed into live virus vaccines. Young birds are most likely to develop illness when infected with these strains. The mesogenic form is associated with an acute respiratory illness of moderate severity that is sometimes associated with life-threatening nervous system complications. Neurotropic velogenic strains are associated with respiratory and neurological disease, such as paralysis of the legs. In outbreaks, death can occur in 5–10 percent or more of infected birds. Viscerotropic-velogenic strains cause an acute, often lethal, infection with hemorrhagic gastrointestinal lesions. In outbreaks, mortality rates can be as high as 90 percent.

Virulence of NDV is dependent on the amino acid sequence of the cleavage site of the F protein (Glickman et al. 1988), which determines the ability of the F protein to be cleaved by cellular proteases (Gotoh et al. 1992). Mesogenic or velogenic strains have dibasic amino acids in the F protein cleavage sequence, while the F proteins of lentogenic NDV strains do not have this motif (Glickman et al. 1988).

Both wild-type and vaccine strains of NDV can infect humans (Chang 1981). After an incubation period of 1–4 days, the patient sometimes develops conjunctivitis, which is usually unilateral and, occasionally, systemic symptoms such as fever, myalgia, and malaise. Symptoms usually resolve within a week.

Epizootiology

NDV can spread by inhalation or ingestion of infectious virus. Large amounts of infectious virus can be excreted in the feces, which is likely to be the source of infectious virus in most instances. NDV can be introduced into new populations through natural movement of infected birds (e.g. migration, shipping infected birds from one location to another) or by fomites such as contaminated food, equipment, or water. The virus can be transmitted quickly and efficiently in crowded populations, such as poultry houses. Humans presumably become infected by contamination of the hands and autoinoculation of the conjunctiva or by inhalation of aerosolized virus. Most human infections have occurred after exposure to wild-type virus in slaughterhouses or laboratories or while administering the vaccine.

Pathology, pathogenesis, and immune response

The virus infects via the respiratory or gastrointestinal tract or the conjunctivae. With virulent strains, the virus first causes a local lytic infection and then the bird becomes viremic and the virus spreads to infect multiple organs, including the brain, heart, kidneys, and reticuloendothelial system. The speed and efficiency with which it infects different tissues seem to be key to its virulence and this, in turn, depends on the host species and strain of NDV. Efficient cleavage of the glycoproteins in a wide range of cell types is characteristic of highly virulent strains (Rott and Klenk 1988). The titer of the inoculum can also alter the course of the infection. A low-titer inoculum can ameliorate disease caused by a virulent strain.

Vaccination or naturally acquired infection confers resistance to further disease. Passively acquired antibody can also provide protection from disease. It has not yet been determined which components of the immune response are responsible for controlling and clearing established infection in the bird.

Laboratory diagnosis

Diagnosis of NDV is often important in the context of control measures that are to be undertaken, and requires isolation and the characterization of the virus as virulent, avirulent, or possibly vaccinelike. Respiratory, fecal, or cloacal specimens from live birds or tissue specimens from affected organs from dead birds can be used to isolate the virus. Cell culture systems or embryonic chicken (or other fowl) eggs from flocks known to be pathogen-free or NDV-free can be used to isolate the virus. The virus is then characterized by determining its virulence in embryonating hens' eggs, day-old chicks or 6-week-old chickens. Molecular methods to characterize strains and track transmission are being developed and may provide alternative ways to determine virulence (Seal et al. 1995; Alexander 1999).

Antibodies against NDV can be detected by a variety of tests, including neutralization, hemagglutination inhibition and enzyme immunoassays (EIA). Antibody tests have been used primarily to demonstrate past infection or a response to vaccination.

Control

Vaccination and transmission control programs have been used to prevent NDV infection. Live virus vaccines developed from B1 or Lasota lentogenic strains are most widely used. For poultry, the vaccines can be administered in a variety of ways: orally in water, by intranasal or intraocular inoculation, or by aerosols. Quarantine of imported birds and quarantine and slaughter of infected flocks have been an integral part of NDV control in a number of countries.

Other avian paramyxoviruses

Eight other serotypes of avian paramyxoviruses have been isolated from a variety of birds. Although NDV is the most important pathogen from an economic standpoint, other viruses in the group have sometimes been associated with serious disease.

HENIPAVIRUSES

Viruses belonging to the recently described genus *Henipavirus* within the family *Paramyxoviridae* emerged during the past decade. These viruses were initially identified as the etiologic agents responsible for outbreaks of febrile respiratory illnesses of veterinary livestock. When transmitted to humans from infected animals, these viruses were responsible for severe encephalitic or respiratory diseases that often had fatal outcomes (Murray et al. 1995a; Chua et al. 2000). The two viruses in this genus, Hendra virus and Nipah virus are different from most other paramyxoviruses because they have a broad host range both in vivo and in vitro. Fruit-eating bats appear to be a natural reservoir for the henipaviruses, although isolation of these viruses from this reservoir has been infrequent. Humans are infected via intermediate hosts such as horses or pigs, by exposure to infected fruit bats, or by direct human-to-human transmission.

Hendra virus is the type species of the genus *Henipavirus*, and both Hendra virus and Nipah virus have genetic characteristics and replication strategies that are similar to those of other members of the subfamily *Paramyxovirinae*. The henipaviruses also have several unique genetic features that distinguish them. The genomes of Hendra virus and Nipah virus are 18 234 and 18 246 nucleotides, respectively, making them the largest paramyxovirus genomes reported (Harcourt et al. 2001; Wang et al. 2000). The increased size is due to a longer open reading frame (ORF) encoding the phosphoprotein (P) and the unusually long nontranslated regions that flank each gene (Harcourt et al. 2000, 2001; Wang et al. 1998, 2000; Yu et al. 1998a,b). The *P* gene of these viruses encodes three nonstructural proteins (C, V, and W) in addition to P. The C protein is encoded by a second ORF that initiates 23 nucleotides downstream of the P ORF translational initiation site (Harcourt et al. 2000; Wang et al. 1998). In addition to the C ORF, HV has another ORF in the *P* gene that encodes a putative, arginine rich, small basic protein (SB) of 65 amino acids (Wang et al. 1998), which has not yet been detected in infected cells (Wang et al. 2001).

The *P* genes of both Hendra virus and Nipah virus contain an RNA editing site that it is identical to the editing site found in measles virus (MeV) (Harcourt et al. 2000; Wang et al. 1998). The addition of a single G allows expression of the V protein, while addition of two Gs allows expression of a protein analogous to the W protein of Sendai virus (Delenda et al. 1998; Harcourt et al. 2000; Vidal et al., 1990). The V and W proteins appear to be virulence factors since cells expressing both V and W of Nipah virus block activation of an IFN-inducible promoter in primate cells (Park et al. 2003). Expression of IFN-α and IFN-γ-driven reporter genes was inhibited by the expression of the V of Nipah virus or HV in the presence of IFN. The V of Nipah virus formed high molecular weight complexes of 300–500 kDa with STAT1 and STAT2, which prevented both the activation and nuclear transportation of STAT1 (Rodriguez et al. 2002, 2003).

The L proteins of the henipaviruses have the six linear domain structures found within the polymerase proteins of all viruses in the order *Mononegavirales*. A highly conserved GDNQ sequence within domain III is conserved in most of the *Mononegavirales* viruses but is changed to GDNE in the henipaviruses and tupaia virus (Poch et al. 1990; Tidona et al. 1999; Harcourt et al. 2000; Wang et al. 2001).

The cleavage site of the fusion (F) protein of the henipaviruses contains a single basic amino acid and thus does not contain the R–X–R/K–R consensus sequence for furin proteases that is seen in the morbilliviruses, rubulaviruses, and pneumoviruses (Lamb and Kolakofsky 2001). The cellular protease(s) that cleaves the F of henipaviruses is unidentified, though basic amino acids are not required for cleavage (Moll et al. 2004). The henipaviruses are unique in that they have a leucine residue at the amino terminus of F_1 instead of the phenylalanine found in most other members of the family *Paramyxoviridae* (Harcourt et al. 2000; Wang et al. 2001). The G proteins of the henipaviruses have no known hemagglutinin or neuraminidase activities (Harcourt et al. 2000; Yu et al. 1998a).

Epidemiology and transmission

Hendra virus has been associated with two human and 17 horse deaths in three separate incidents in Australia during 1994–1999 (Murray et al. 1995a, 1995b; Selvey et al. 1995). The last known incident of Hendra virus infection occurred during January 1999 in Australia and involved a fatality in a single, adult mare, but no human infections (Field et al. 2000; Hooper et al. 2000). Antibodies to Hendra virus were detected in several fruit bat species in Queensland and the virus isolated from a fruit bat was indistinguishable from that isolated from horses and humans (Young et al. 1996; Halpin et al. 1999, 2000) suggesting that these bats may be a natural reservoir for Hendra virus. Transmission to horses may have occurred through the ingestion of material recently contaminated by the urine or infected fetal tissue of fruit bats (Halpin et al. 1999; Field et al. 2000).

The first known human infections with Nipah virus occurred during an outbreak of severe febrile encephalitis in peninsular Malaysia and Singapore in 1998–1999. Direct contact with pigs was the primary source of human infection (CDC 1999a, b; Chua et al. 2000). This outbreak began in October 1998 near the city of Ipoh and then spread southward in conjunction with the movement of pigs, resulting in three other clusters of human disease near Kuala Lumpur. In Singapore, abattoir workers who slaughtered pigs imported from outbreak-affected areas in Malaysia were exclusively affected (Paton et al. 1999; Chew et al. 2000). A total of 265 patients (104 fatal) with viral encephalitis and 11 patients (one fatal) with laboratory-confirmed Nipah virus disease were reported in Malaysia and Singapore, respectively. Adult males who were primarily involved in pig farming or pork production activities accounted for the majority of cases. Although Nipah virus is excreted in respiratory secretions and urine of patients (Chua et al. 2001), a survey of healthcare workers in Malaysia demonstrated no evidence of human-to-human transmission (Mounts et al. 2001).

Because of the virologic similarities between Nipah virus and Hendra virus, surveillance for the natural reservoir for Nipah virus was focused on bats. Neutralizing antibodies to Nipah virus were found in four fruit-bat species and one insectivorous-bat species in peninsular Malaysia (Yob et al. 2001), and antibodies have been detected in Cambodian bats (Olson et al. 2002). Nipah virus has recently been isolated from the urine of Malaysian fruit bats roosting on Tioman Island (Chua et al. 2002).

Nipah virus has been established as the cause of fatal, febrile encephalitis in human patients in Bangladesh during the winters of 2001, 2003, and 2004. A Nipah virus-like virus was identified as the cause of the outbreaks in 2001 and 2003 based on results from serologic testing (Hsu et al. 2004); however, Nipah virus was isolated from patients with acute disease in 2004. Though antibodies to Nipah virus were detected in fruit bats from the affected areas in 2004, an intermediate animal host was not identified. It is likely that the virus was transmitted directly from bats to humans. Human-to-human transmission of Nipah virus was also documented during the outbreak in Bangladesh (ICDDRB 2004a,b; WHO 2004).

Clinical and pathological manifestations

Little is known concerning the clinical disease and associated pathology in the natural hosts of the henipaviruses, and studies are in progress to further address these questions. Natural or experimental Hendra virus infections of bats are asymptomatic though the bats seroconvert and viral antigen and some live virus can be detected (Williamson et al. 1998; Halpin et al. 2000; Field et al. 2001). Horses and cats naturally infected with Hendra virus show clinical signs that include depression, anorexia, profuse nasal discharge, and labored breathing with pulmonary edema and congestion. Pneumonic and hemorrhagic lesions are seen in the lungs and death occurs within 2 days of infection. Virus can be isolated from the urine of infected animals (Williamson et al. 1998; Field et al. 2001). Experimental infection of horses was less severe than natural disease. Nipah virus infection of golden hamsters results in fatal neurological disease, thus providing a small animal model for studying the pathogenesis of Nipah virus (Wong et al. 2003).

In the first reported cases of Hendra virus infection in humans, patients had abrupt onset of an influenza-like illness, characterized by myalgia, headaches, lethargy, and vertigo (Selvey et al. 1995). Based on the exposure history of the two people involved, the incubation period for the acute disease caused by Hendra virus is approximately 5–7 days. One patient remained lethargic for 6 weeks but recovered fully, while the other succumbed to infection. In the second reported Hendra

virus incident, the single patient initially presented with features of meningitis, including headache, drowsiness, vomiting, and neck stiffness. Following complete recovery, this patient presented 13 months later with neurological disease and died shortly thereafter.

The onset of Nipah virus disease is abrupt, usually with the development of fever and severe encephalitis. Fever (97 percent), headache (65 percent), dizziness (36 percent), vomiting (27 percent), and reduced level of consciousness (21 percent) were the most common clinical features noted during the outbreaks in Malaysia and Singapore (Goh et al. 2000). In addition to the neurological symptoms described above, acute respiratory distress was also noted in many patients during the Nipah virus outbreak in Bangladesh in 2004 (ICDDRB 2004a, b). The exact incubation period of Nipah virus disease in humans is not known but ranged from several days to 2 months, and was 2 weeks or less in the majority of patients.

The pathogenesis of Hendra virus in humans showed a severe interstitial pneumonia (Selvey et al. 1995; Murray et al. 1995a) and leptomeningitis (O'Sullivan et al. 1997). In contrast, a multiorgan vasculitis associated with infection of endothelial cells was the main pathologic feature of Nipah virus infection (Parashar et al. 2000) with infection being most pronounced in the central nervous system with necrotic foci of neuronal degeneration. Evidence of endothelial infection and vasculitis was also seen in other organs, including the lung, heart, spleen, and kidney. Nipah virus has been isolated from cerebrospinal fluid, tracheal secretions, throat swab, nasal swab, and urine specimens of patients (Goh et al. 2000; Chua et al. 2001).

During the outbreak in Malaysia, direct contact with pigs was the primary source of human Nipah virus infection, with no evidence of human-to-human transmission (Parashar et al. 2000). Although pigs showed extensive infection of the upper and lower airways, with evidence of tracheitis, and bronchial and interstitial pneumonia, the mortality rate was less than 5 percent. A harsh, nonproductive cough (called the mile-long cough) was a prominent clinical feature, but other signs such as lethargy or aggressive behavior indicated some neurological involvement (Chua et al. 2000; Hooper and Williamson 2000; Hooper et al. 2000). Serologic studies demonstrated evidence of infection among other species of animals, including dogs and cats on and near farms with Nipah virus-infected pigs (Chua et al. 2000; Hooper et al. 2000), though it is unclear whether humans were at risk from exposure to infected animals other than pigs (Goh et al. 2000; Parashar et al. 2000).

Control

Since interruption of transmission of Hendra and Nipah viruses from their reservoirs to intermediate hosts or directly to humans is difficult, early identification of infected animals and humans and use of appropriate personal protective equipment in healthcare and agricultural settings are the keys to prevention. Since person-to-person transmission of Nipah virus has been documented, those in contact with patients, including healthcare workers, should use standard droplet precautions during contact with secretions, excretions, and body fluids of patients.

No vaccines or antiviral drugs are currently available for Hendra virus or Nipah virus. In vitro, ribavirin has a demonstrated antiviral effect against Hendra virus. During the Nipah virus outbreak in Malaysia, patients receiving ribavirin either orally or intravenously showed a lower mortality rate (Chong et al. 2001).

Laboratory diagnosis

Analysis of serum samples from outbreaks indicated that Nipah virus and Hendra virus infections generate a humoral immune response in humans. IgM was present in serum shortly after the onset of Nipah virus infection and nearly all patients were antibody-positive by the third day (Ramasundrum et al. 2000). IgG was detected 10–29 percent of Nipah virus-infected patients within the first 10 days of illness, and in 100 percent of patients after 17–18 days.

Because of their ability to cause severe disease in animals and humans, work with live Nipah virus and Hendra virus must be conducted at BSL-4. ELISA assays to detect IgG and IgM antibodies are routinely used to detect Hendra virus and Nipah virus infections. These assays often use inactivated or expressed antigens and, therefore, have the advantage that they do not need to be conducted at BSL-4. Also, IgG antibodies can be detected by using standard serum neutralization tests. Immunohistochemistry has proven extremely useful for detecting Nipah virus antigens in fixed tissue samples. Both Hendra virus and Nipah virus can be isolated on Vero-E6 cells from cerebrospinal fluid, nasal samples, and urine samples from infected individuals (Goh et al. 2000; Chua et al. 2001). Various RT-PCR assays have been used to detect RNA from Hendra virus and Nipah virus in a variety of clinical samples and tissues (Halpin et al. 2000; Daniels et al. 2001; Guillaume et al. 2004).

RUBULAVIRUSES

Several viruses in the genus *Rubulavirus* have been isolated from animals. During the search for the reservoir of Nipah virus in Malaysia, a previously undescribed rubulavirus, Tioman virus, was isolated from a small number of fruit bats. Tioman virus has not been associated with disease in bats or any other animal (Chua et al. 2002). Menangle virus is antigenically related to Tioman virus, and was originally isolated from stillborn piglets in a piggery in New South Wales Australia in 1997. Infections resulted in degeneration of

the brain and spinal cord and an increase in the number of abortions and stillbirths associated with deformities. Fruit bats living near the affected piggeries were seropositive for antibodies to Menangle virus. Two of over 250 humans who worked in the piggery also had antibodies to Menangle virus and reported an influenza-like illness following exposure to the infected pigs (Chant et al. 1998; Philbey et al. 1998). No further outbreaks of Menangle virus have been reported. Another porcine paramyxovirus, La-Piedad Michoacan-Mexico virus (LPMV), was identified as the agent responsible for fatal disease in piglets and has been endemic in Mexico since 1980. Bats do not play a role in the tranmission of LPMV (Linne et al. 1992; Salas-Rojas et al. 2004). Another respirovirus, Mapuera virus, has also been detected in bats (Henderson et al. 1995).

UNASSIGNED PARAMYXOVIRUSES

A number of new paramyxoviruses have been isolated recently from various animal species, but have not yet been assigned to a genus. Sixteen paramyxovirus isolates from reptilian species (Ahne et al. 1999) have been described; the archetype is fer-de-lance virus, which causes highly pathogenic respiratory infections in snakes. This virus has been completely sequenced and has a novel gene located between the *N* and *P* genes, which has no counterpart in any of the other viruses of the family. Fer-de-lance virus has been proposed as the type species for a new genus, *Ferlavirus*, within the subfamily *Paramyxovirinae* (Kurath et al. 2004). A number of paramyxoviruses have been isolated from rodents, including Nariva virus and Mossman virus (Roos and Wollmann 1979; Miller et al. 2003). Tupaia virus was discovered in a cell line derived from tree shrews (Tidona et al. 1999) and Salem virus was isolated from the mononuclear cells of a horse during an outbreak of disease in the USA in 1992 (Renshaw et al. 2000). Mossman, Tupaia, and Salem viruses are unclassified members of the subfamily *Paramyxovirinae* that are most closely related to the morbilliviruses and henipaviruses (Miller et al. 2003). The natural distribution and pathogenic potential of these novel paramyxoviruses are mostly unexplored.

PROPERTIES OF THE VIRUSES

Introduction

Coronaviruses, toroviruses, and arteriviruses are enveloped, positive-strand RNA viruses that infect vertebrates and can cause disease in their natural hosts. The genome organization and replication strategy are similar in all three groups of viruses but the differences in morphology and in genome size of the arteriviruses clearly set them apart. Coronaviruses and toroviruses are usually associated with respiratory or enteric disorders, although other organs (for example, the central nervous system (CNS)) can also be involved. The outcome of arterivirus infection can range from an asymptomatic, persistent carrier-state to lethal hemorrhagic fever.

The combination of features that distinguishes coronaviruses, toroviruses, and arteriviruses from other positive-strand RNA viruses are primarily in the structure and function of the replicase gene:

- The replicase gene comprises two overlapping open reading frames (ORF), and expression of the downstream ORF is mediated by –1 ribosomal frameshifting.
- Sequence analysis has identified common coding regions, e.g. motifs characteristic of proteinase, polymerase, helicase, and endoribonuclease, that are located at specific positions within the replicase gene. The signature organization of these domains can be expressed as (M-3CL-M)–RdRp–(Zn-HEL)–NendoU, where M-3CL-M represents a chymotrypsin-like proteinase (with a substrate specificity resembling that of picornavirus 3C proteinases) flanked by two hydrophobic transmembrane domains, RdRp is RNA-dependent RNA polymerase, (Zn-HEL) is a putative multinuclear Zn-finger-like domain associated with a superfamily 1 helicase domain and NendoU is a uridylate-specific endoribonuclease.
- In the infected cell, viral gene expression is mediated by a set of four or more 3′ co-terminal subgenomic mRNAs. Only the ORFs contained within the 5′ unique regions of each mRNA, i.e. the regions not found in the next smallest mRNA, are expressed as protein.

The features that distinguish coronaviruses, toroviruses, and arteriviruses from each other are two-fold:

1. There are significant differences in structure and function of the nucleocapsid protein gene. The molecular weights of the nucleocapsid protein are 50–60 kDa for coronaviruses, ca. 19 kDa for toroviruses and 12–14 kDa for arteriviruses. The nucleocapsid structure also has different morphologies: helical-spherical for coronaviruses, helical-tubular for toroviruses, and isometric for arteriviruses.
2. In addition to the common motifs listed above, coronaviruses and toroviruses have motifs indicative of additional replicase gene functions related to RNA processing. These include a putative exonuclease (ExoN), 2′-*O*-ribose methyl transferase (2-*O*-MT) and cyclic phophodiesterase (CPD).

A number of other features help to define and distinguish these three groups of viruses. They include the organization of the virus genome, genome size, evidence of discontinuous RNA synthesis during subgenomic mRNA production, the structure and function of the virus envelope (glyco)proteins and the intracellular budding of virus particles (de Vries et al. 1997; Gonzalez et al. 2003; Holmes 2001a; Lai and Holmes 2001; Snijder et al. 2003a; Snijder and Meulenberg 1998; van Vliet et al. 2002; Ziebuhr et al. 2000).

Classification

At the present time the coronaviruses and the toroviruses represent two genera of the family *Coronaviridae*. The arteriviruses are designated as a separate, monogeneric family, the *Arteriviridae* (they were previously assigned to the family *Togaviridae*). The families *Coronaviridae* and *Arteriviridae* are united in the order *Nidovirales* (Cavanagh 1997). The viruses that currently comprise the families *Coronaviridae* and *Arteriviridae* are listed, with their abbreviations and natural hosts, in Table 1.

Twenty four viruses are now classified as species in the *Coronaviridae* (Spaan et al. 2005). The prototype of the genus *Coronavirus* is avian *Infectious bronchitis virus* (IBV). The name coronavirus is derived from the solar coronalike (Latin *corona*: crown) appearance of virus particles in negatively stained electron micrographs. The prototype of the genus *Torovirus* is *Equine torovirus* (previously Berne virus), the name torovirus being derived from the curved tubular (Latin *torus*: lowest convex molding in the base of a column) morphology of the nucleocapsid structure. In addition to the viruses listed in Table 1, a further coronavirus, rabbit coronavirus (RbCoV) is considered as a tentative species of the genus and there have been recent reports of a novel human coronavirus, HCoV-HKUI (Woo et al. 2005) and a bat coronavirus, BaCoV (Poon et al. 2005). Also, although *Feline infectious peritonitis virus* (FIPV), *Sialodacryoadenitis virus* (SDAV), *Human coronavirus NL63* (HCoV-NL63), and *Porcine respiratory coronavirus* (PRCoV) are now recognized as coronavirus species,

Table 1 *Coronaviruses, toroviruses, and arteriviruses*

Natural host	Virus	Abbreviation
Coronaviruses		
Chicken	*Infectious bronchitis virus*	IBV
Cattle	*Bovine coronavirus*	BCoV
Dog	*Canine enteric coronavirus*	CCoV
Cat	*Feline coronavirus*	FCoV
Cat	*Feline infectious peritonitis virus*	FIPV
Humans	*Human coronavirus 229E*	HCoV-229E
Humans	*Human coronavirus NL63*	HCoV-NL63
Humans	*Human coronavirus OC43*	HCoV-OC43
Humans	*SARS-coronavirus*	SARS-CoV
Humans	*Human enteric coronavirus*	HECoV
Mouse	*Murine hepatitis virus*	MHV
Rat	*Rat coronavirus*	RtCoV
Rat	*Sialodacryoadenitis virus*	SDAV
Pig	*Porcine epidemic diarrhoea virus*	PEDV
Pig	*Transmissible gastroenteritis virus*	TGEV
Pig	*Porcine hemagglutinating encephalomyelitis virus*	HEV
Pig	*Porcine respiratory coronavirus*	PRCoV
Turkey	*Turkey coronavirus*	TCoV
Pheasant	*Pheasant coronavirus*	PhCoV
Shearwater	*Puffinosis coronavirus*	PCoV
Toroviruses		
Horse	*Equine torovirus*	EToV
Cattle	*Bovine torovirus*	BToV
Humans	*Human torovirus*	HToV
Pig	*Porcine torovirus*	PToV
Arteriviruses		
Horse	*Equine arteritis virus*	EAV
Mouse	*Lactate dehydrogenase-elevating virus*	LDV
Monkey	*Simian haemorrhagic fever virus*	SHFV
Pig	*Porcine reproductive and respiratory syndrome virus*	PRRSV

limited sequence data suggests that they could also be considered as variants of *Feline coronavirus* (FCoV), RtCoV, *Human coronavirus 229E* (HCoV-229E), and *Transmissible gastroenteritis virus* (TGEV), respectively. The sequence relationships of coronaviruses and toroviruses have been analyzed in detail (Gonzalez et al. 2003) and a revision of the current taxonomy is expected.

Four viruses are classified as species in the *Arteriviridae* (Snijder et al. 2005). The prototype of the family is *Equine arteritis virus* (EAV). The name arterivirus is derived from arteritis (inflammation of an artery), a disease caused by EAV. Previously, *Porcine respiratory and reproductive syndrome virus* (PRRSV) was also referred to as swine infertility and respiratory syndrome virus (SIRSV) or Lelystad virus. The four arterivirus species are antigenically distinct and no detailed serological cross-reactions have been reported. Phylogenetic analysis of arterivirus replicase proteins indicates that the four arterivirus species each constitute a branch within the genus, with each species represented by a cluster of strains. *Lactate dehydrogenase-elevating virus* (LDV) and PRRSV are most closely related to each other.

Finally, it should be mentioned that sequence analysis of *Gill-associated virus* (GAV) and *Yellow head virus* (YHV), which infect prawns, indicates that they are related to coronaviruses, toroviruses, and arteriviruses (Cowley et al. 2000) and justifies placing them in a genus *Okavirus* in the family *Roniviridae* in the order *Nidovirales* (Gonzalez et al. 2003). However, these viruses will not be discussed further in this chapter.

Morphology and structure

Coronaviruses are pleomorphic but roughly spherical enveloped particles, 120–160 nm in diameter with a characteristic 'fringe' of surface projections 20 nm long. An inner 'fringe' of short surface projections is sometimes seen on murine hepatitis virus (MHV), bovine coronavirus (BCoV), turkey coronavirus (TCoV), and human coronavirus OC43 (HCoV-OC43) particles. Toroviruses are also pleomorphic, enveloped particles, 120–140 nm in diameter; they are disk-, kidney- or rod-shaped and, like the coronaviruses, are decorated with 15–20 nm surface projections. The nucleocapsid of both coronaviruses and toroviruses is helical but differs in morphology. Coronavirus nucleocapsids are extended when the structure is relaxed but they may be organized into spherical, possibly icosahedral, superstructures in the virus particle (Escors et al. 2001; Risco et al. 1996; Salanueva et al. 1999). A gap separating the internal core from the envelope has been observed in coronaviruses using cryo-electron microscopy. The nucleocapsids of toroviruses are tubular. Arteriviruses are 45–60 nm in diameter and consist of an isometric nucleocapsid of 25–35 nm that is surrounded by a lipid envelope. No prominent surface projections are seen on the virion but a surface pattern of relatively small and indistinct projections has been observed. The morphological features and the assignment of structural proteins to the coronavirus, torovirus, and arterivirus virions are illustrated in Figure 1.

Coronaviruses have an estimated molecular mass of 400×10^6 kDa and a buoyant density in sucrose of 1.15–1.20 g/cm^3. The buoyant density in CsCl is 1.23–1.24 g/cm^3 and the sedimentation coefficient $S_{20,w}$ is 300–500. Coronaviruses are sensitive to heat, lipid solvents, non-ionic detergents, formaldehyde, oxidizing agents, and UV-irradiation. Some coronaviruses are resistant to acid pH and/or dessication. Toroviruses have a buoyant density of 1.14–1.18 g/cm^3 in sucrose and an estimated sedimentation coefficient ($S_{20,w}$) of 400–500. Virus infectivity is stable between pH 2.5 and 9.7 but rapidly inactivated by heat, organic solvents, and irradiation. Arteriviruses have a buoyant density in sucrose of 1.13–1.17 g/cm^3 and 1.17–1.20 g/cm^3 in CsCl. The sedimentation coefficient is 214S–230S. Temperature, pH, and lipid solvents affect virion stability and virions are highly unstable in solutions containing low concentrations of detergents.

Genome structure and function

The genome of coronaviruses and toroviruses is a positive-strand RNA molecule of ca. 27 000–31 500 nucleotides (nt). This estimate of size is based on the nucleotide sequence of nine complete coronavirus genomes and the nucleotide sequence of the equine torovirus (EToV) genome (see www.ncbi.nlm.nih.gov/entrez/) (van Vliet et al. 2002). The coronavirus and torovirus genomic RNAs have a 5′ cap structure, and are polyadenylated at their 3′ end. It is generally accepted that the genomic RNA of coronaviruses and toroviruses is infectious, a conclusion that is based on the initiation of infection in susceptible cells with RNA extracted from purified virions and the initiation of infection with transcripts from cDNA clones corresponding to full-length coronavirus genomic RNA (Almazan et al. 2000; Casais et al. 2001; Thiel et al. 2001a; Yount et al. 2000; Yount et al. 2003; Yount et al. 2002).

The positive-strand RNA genome of arteriviruses is significantly smaller than that of coronaviruses and toroviruses. Sequence analysis of the EAV, LDV, and PRRSV genomes indicates a size of ca. 12 700–15 700 nt (see www.ncbi.nlm.nih.gov/entrez/). The genomic RNA of arteriviruses is polyadenylated at the 3′ end. It has been reported that the genomic RNA of simian haemorrhagic fever virus (SHFV) has a 5′ cap structure (Sagripanti et al. 1986). Cap analogue was found to be an essential component of the in vitro transcription reactions used to generate infectious RNA from PRRSV and EAV full-length cDNA templates (Meulenberg et al. 1998; van Dinten et al. 1997).

REGULATORY ELEMENTS

The genomes of coronaviruses and toroviruses contain a 5′ non-translated region (NTR) of several hundred

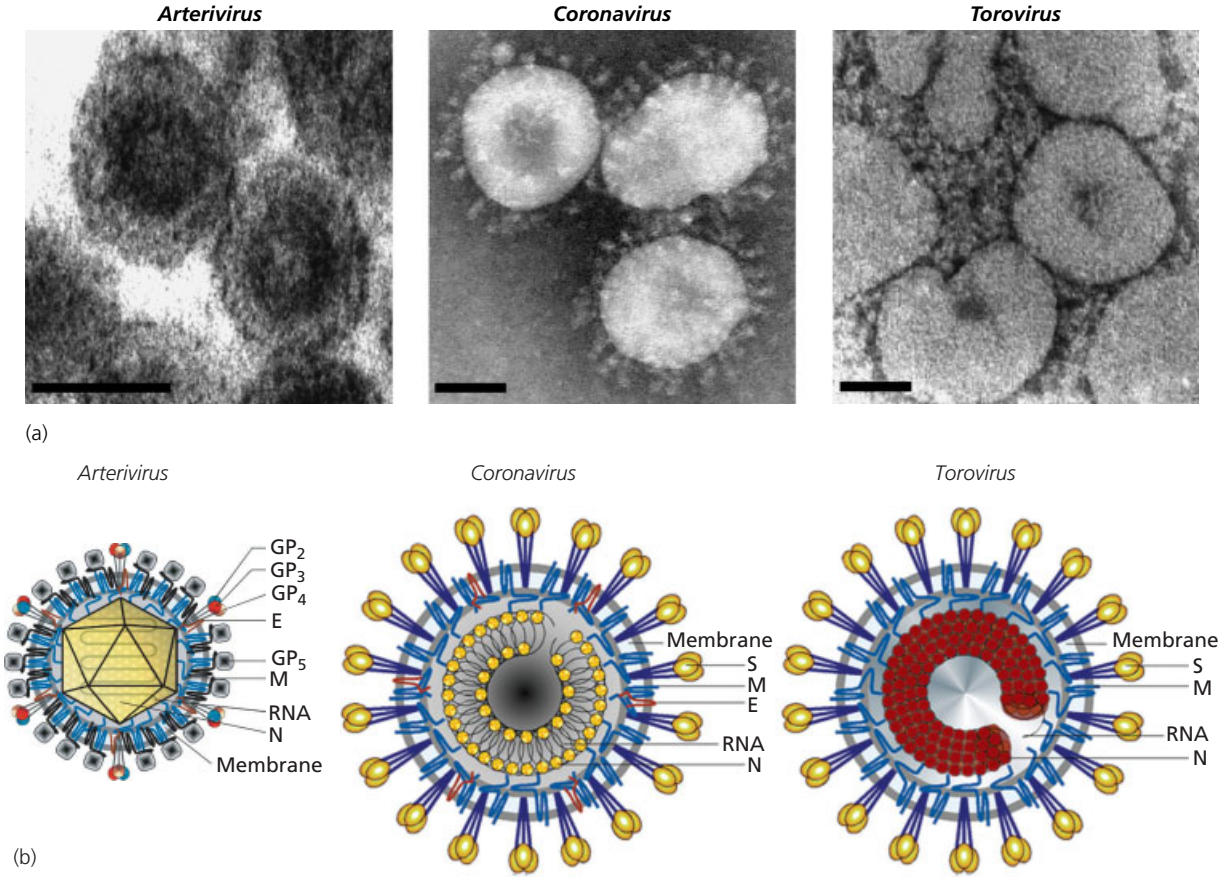

Figure 1 *Electron micrographs and schematic representations of coronavirus, torovirus, and arterivirus virion structure showing the locations of the structural proteins. The stoichiometry of the virion components is shown arbitrarily. E, envelope protein; GP_5, major glycoprotein; GP_2, GP_3, GP_4, minor glycoproteins; M, membrane protein; N, nucleoprotein; S, spike glycoprotein. The scale bar represents 50 nm.*

nucleotides. This region is almost devoid of AUG codons but a small ORF of 3–11 codons is conserved in the 5′ NTR of viruses examined to date. It has been speculated that this 'mini-ORF' may play a role in regulating translation from the genomic RNA (Senanayake and Brian 1999). The 5′ NTR of arteriviruses is relatively short, about 150–220 nt. Although small ORFs have been identified in this region for EAV, PRRSV, and SHFV (Snijder and Meulenberg 1998). The EAV intra-leader ORF was shown to be completely dispensable for EAV replication in cell culture (Molenkamp et al. 2000).

By analogy with other positive-strand RNA viruses, it can be expected that secondary (or tertiary) structures in the 5′ NTR of coronaviruses, toroviruses, and arteriviruses will have a role in the synthesis and packaging of virus RNA. Van den Born and colleagues (2004) have predicted and analyzed the secondary structure of the 5′ proximal region of the EAV genome. Their analysis suggests that secondary structures in this region play a role in the promotion of nidovirus plus-strand RNA synthesis from genomic and subgenomic templates. It remains to be shown exactly which of the predicted structural elements are involved and if, for example, additional RNA–protein interactions are important. Similar secondary structures have also been predicted in the 5′ NTR of other arteriviruses, coronaviruses, and toroviruses (Chang et al. 1996; Shieh et al. 1987; Van den Born et al. 2004).

As is described in more detail in the section 'Transcription,' coronavirus and arterivirus gene expression is mediated by the production of a set of subgenomic mRNAs in the infected cell. An element that plays an important role in this process is the so-called transcription-regulating sequence (TRS). In coronaviruses and toroviruses, this motif is a species-specific AU-rich sequence of ca. 10 nt, located within the 5′ NTR and upstream of the ORFs that are destined to become 5′ proximal in the subgenomic mRNAs. In the arteriviruses, the motif is also an AU-rich, species-specific sequence of 6 nt. Secondary structure predictions of the 5′ NTR of many coronaviruses and arteriviruses (Van den Born et al. 2004) places the 5′ TRS (which is termed the leader TRS, see below) in a hairpin loop structure referred to as the 'leader TRS hairpin' or LTH. This structure is thought to be critical for the process of discontinuous RNA synthesis that takes place during the

production of coronavirus and arterivirus virus minus-strand RNA.

As for many other viruses, the packaging of coronavirus and arterivirus genomes is a process that involves the interaction of virus structural proteins and elements in the genomic RNA. It has been shown for the coronaviruses MHV and BCoV that the packaging of genomic RNA is, at least partially, mediated by an RNA element located at the 3′ end of the replicase gene (Cologna and Hogue 2000; Fosmire et al. 1992). In contrast, the packaging signal of TGEV has been located at the 5′ end of the genome, specifically, within the first 640 nt (Escors et al. 2003). Also, it has been shown that DI-RNA sequences from the 5′ and 3′ NTR of IBV are required for minigenome incorporation into viral particles (Dalton et al. 2001). It is possible that for some coronaviruses, the packaging signal may be comprised of multiple elements but more data are needed to resolve this apparent discrepancy. The packaging signals of arteriviruses have not been mapped.

The 3′ NTR of coronaviruses and arteriviruses comprises 60–150 nt (arteriviruses) or 200–500 nt (coronaviruses and toroviruses) following the last functional ORF and preceding the polyadenylate tract. It can be expected that secondary (or tertiary) structures in the 3′ NTR will have important roles in virus replication. Indeed, at the very 3′ end of the MHV 3′ NTR an extensive complex structure containing multiple stem loops and bulges has been identified and shown to have a role in DI-RNA replication (Liu et al. 2001). This structure incorporates a common motif, $^{G}/_{U}$GGAAGAGC$^{U}/_{C}$, that is found 70–80 nt from the 3′ end of all coronavirus 3′ NTRs examined to date. Also, the 3′ NTR of the MHV and BCoV genomes has been shown to include phylogenetically conserved structures, the 3′ NTR bulged stem loop and the 3′ NTR pseudoknot, that are postulated to represent a molecular switch that controls an, as yet unidentified, aspect of viral RNA synthesis (Goebel et al. 2004). There has been no detailed analysis of the arterivirus 3′ NTR and the only significant nucleotide sequence conservation that has been found in the 3′ NTR is located immediately upstream of the polyadenylate tract. However, it has become clear that RNA signals involved in arterivirus replication extend into the coding sequences in the 3′-proximal region of the genome (Molenkamp et al. 2000). In the case of PRRSV, a so-called 'kissing interaction' between the loop sequences of RNA hairpin structures in the 3′ NTR and the nucleocapsid protein gene was recently found to be crucial for minus-strand RNA synthesis (Verheije et al. 2002b).

OPEN READING FRAMES

The available data suggest that coronavirus and arterivirus genomes contain between six and 14 functional ORFs. The easiest to define are those located toward the 3′ end of the genome, encoding the structural proteins (Figure 2). For coronaviruses and toroviruses, these are the spike (S), membrane (M), and nucleocapsid protein (N) ORFs and for the arteriviruses these are ORFs encoding the major surface glycoprotein (GP_5), three minor glycoproteins (see the section on structural proteins) and the envelope (E), membrane (M), and nucleocapsid (N) proteins. The gene order, 5′-surface glycoprotein(s) ORF(s)/membrane protein ORF/nucleocapsid protein ORF-3′, is conserved in the genome of all coronaviruses and arteriviruses studied to date.

The genomes of coronaviruses contain a fourth structural protein ORF, encoding the E (envelope) protein, located 5′ proximal to the M protein ORF. The genomes of toroviruses and a subset of coronaviruses (e.g. HCoV-OC43, MHV, BCoV) also contain an additional structural protein gene, the hemagglutinin-esterase (HE) ORF. The location of this ORF in coronaviruses is 5′ proximal to the *S* protein gene, and in toroviruses it lies between the *M* and *N* protein genes (Cornelissen et al. 1997; Snijder et al. 1991). It seems that the *HE* gene is not essential and may be converted to a pseudogene; for example, during prolonged passage of virus in tissue culture. Recently, it has been suggested that the SARS-coronavirus (SARS-CoV) genome encodes an additional structural protein (currently known as the 3a protein) that is associated with the spike glycoprotein (Zeng et al. 2004).

In the arteriviruses, the glycoprotein encoded by the PRRSV ORF2a, its homologues encoded by ORF2b in EAV and LDV, as well as the EAV and PRRSV ORF3 and ORF4 glycoproteins, were experimentally identified as minor virion components (de Vries et al. 1992; Faaberg and Plagemann 1995; Meulenberg and Petersen-den Besten 1996; Snijder et al. 1999; van Nieuwstadt et al. 1996; Wieringa et al. 2002). It should be noted that the PRRSV ORF3 glycoprotein was suggested to be a minor structural glycoprotein in a European PRRSV isolate (van Nieuwstadt et al. 1996) but a nonstructural protein in a Canadian isolate (Mardassi et al. 1998). Finally, a small, nonglycosylated envelope protein, encoded by ORF2a in EAV and ORF2b in PRRSV, was detected in virus particles and designated E (for envelope) protein (Snijder et al. 1999; Wu et al. 2001).

In the SHFV genome, the region corresponding to that between ORF 1b and ORF 5 in the other three arteriviruses contains three additional ORFs, covering about 1.6 kb (Smith et al. 1997). On the basis of limited sequence similarities, it was postulated that these SHFV ORFs (named ORFs 2a, 2b, and 3) have arisen from the duplication of the SHFV homologues of EAV/LDV/PRRSV ORFs 2–4 by an RNA recombination event (Godeny et al. 1998). Except for this putative triple gene duplication in SHFV, the genetic composition and gene order of all arteriviruses are identical.

With respect to ORFs that encode nonstructural proteins, the corona- and arterivirus genome is dominated by the replicase gene (also referred to as the RNA polymerase gene or RNA polymerase locus). The

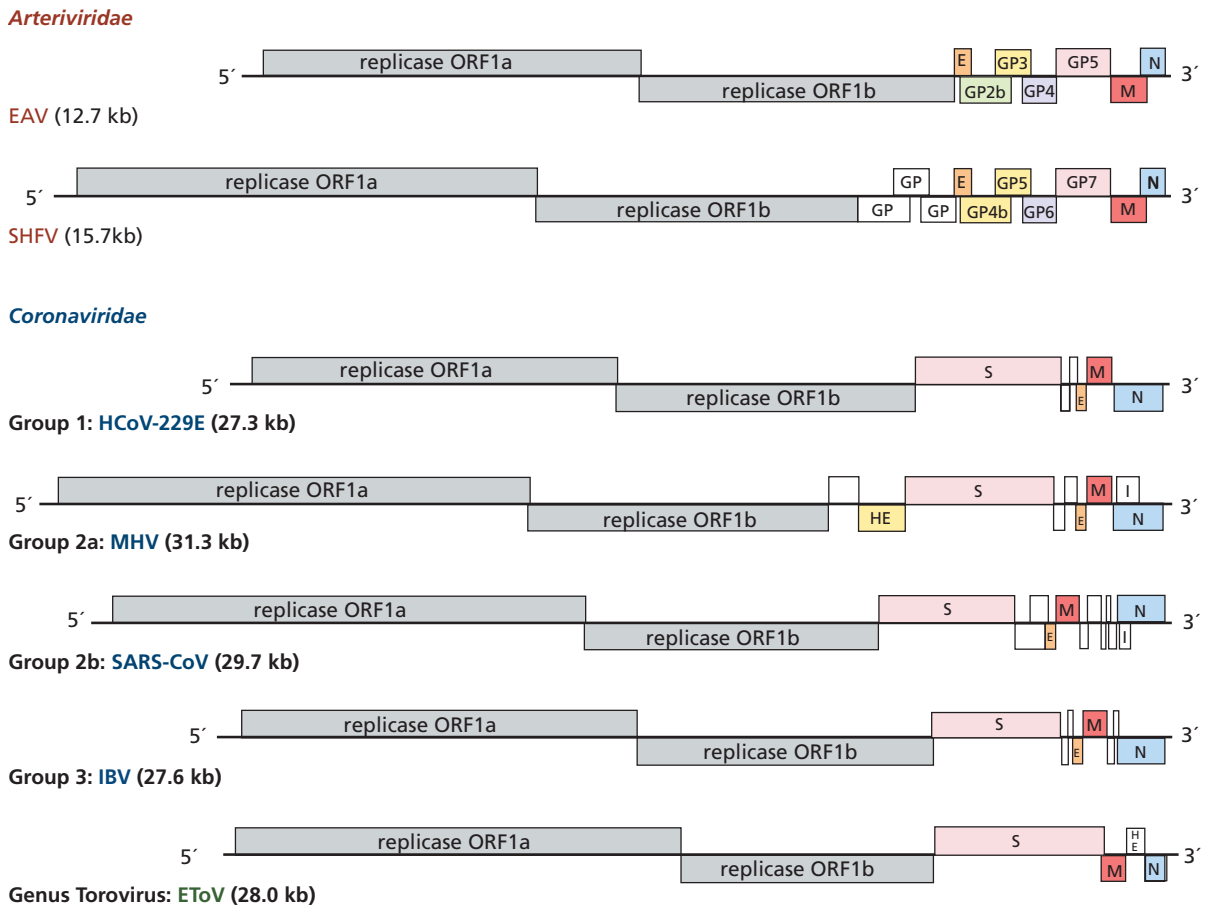

Figure 2 *Genomic structure of coronaviruses, toroviruses, and arteriviruses. The genomic ORFs of representative arteri- and coronaviruses are indicated and the names of the replicase protein and structural protein genes are given. References to the nomenclature of the accessory protein genes can be found in the text. Note that the* HE *protein gene of EToV is a pseudogene but that a functional HE protein is expressed from the BToV genome (Cornelissen et al. 1997). Note also that the arterivirus and coronavirus genomes are drawn to different scales.*

replicase gene consists of two large ORFs encompassing ca. 10 000 nt (arteriviruses) or 20 000 nt (coronaviruses and toroviruses) toward the 5′ end of the genome. These ORFs, ORF1a and ORF1b, overlap in the –1 reading frame. The extent of the overlap varies but invariably encompasses a specific sequence motif, UUUAAAC (or GUUAAAC in the case of EAV), which is referred to as the 'slippery' sequence. Immediately downstream of the slippery sequence is a characteristic RNA structure, the pseudoknot, which can be formed by base pairing. Together, these two elements mediate –1 ribosomal frameshifting during expression of the replicase gene (Brierley 1995). The translation products of the 1a and 1b ORFs are extensively processed by virus-encoded proteinases and, as described below in the section entitled Replicase, produce a large number of proteins that assemble to form a functional replication-transcription complex.

In contrast to the replicase gene, the pattern and arrangement of the remaining nonstructural protein ORFs in the genomes of nidoviruses depend on the virus genus. In the toroviruses and arteriviruses, there is no evidence for nonstructural genes other than the replicase gene. In the coronaviruses there is a diverse and complex pattern of nonstructural genes, even for viruses that are considered to be closely related. The reasons for this complexity are probably two-fold. First, many coronavirus genes seem to encode proteins with accessory functions. Thus, under certain conditions (for example, adaptation and propagation in cultured cells), mutations accumulate which lead to the inactivation and even deletion of these genes. Second, not only divergence from a common ancestor but also RNA recombination seems to have been a major driving force in the evolution of nidoviruses (see also The order *Nidovirales*). It is particularly interesting to note that the SARS-CoV genome encodes a large number of nonstructural proteins that are probably not involved in RNA synthesis and that many of the ORFs encoding these proteins appear to have no counterparts in other coronaviruses.

Replication

A hallmark of the order *Nidovirales* is the production of a set of multiple, subgenomic, 3′ co-terminal mRNAs in

the infected cell. The subgenomic mRNAs are synthesized in nonequimolar amounts but in relatively constant proportions throughout the replication cycle. The structural relationship of these subgenomic mRNAs to the genomic RNA is illustrated for MHV, EAV, and EToV in Figure 3. The replication of the coronavirus MHV and the arterivirus EAV have been studied most intensively and it is assumed that these viruses set a paradigm for other nidoviruses. However, it is also clear that the replication of coronaviruses, toroviruses, and arteriviruses differs, at least in some details. One particularly notable difference is the fact that, in contrast to the subgenomic mRNAs of coronaviruses and arteriviruses, all but the largest of the subgenomic transcripts of toroviruses lack a 5′ leader sequence derived from the 5′-proximal region of the genome (see below).

TRANSCRIPTION

The process by which nidoviruses generate multiple subgenomic mRNAs in the infected cell is complex and not fully understood. A detailed description of the extensive and sometimes conflicting literature in this area is beyond the scope of this chapter and only a summary of the most important aspects is presented here. For more information, the reader is referred to the

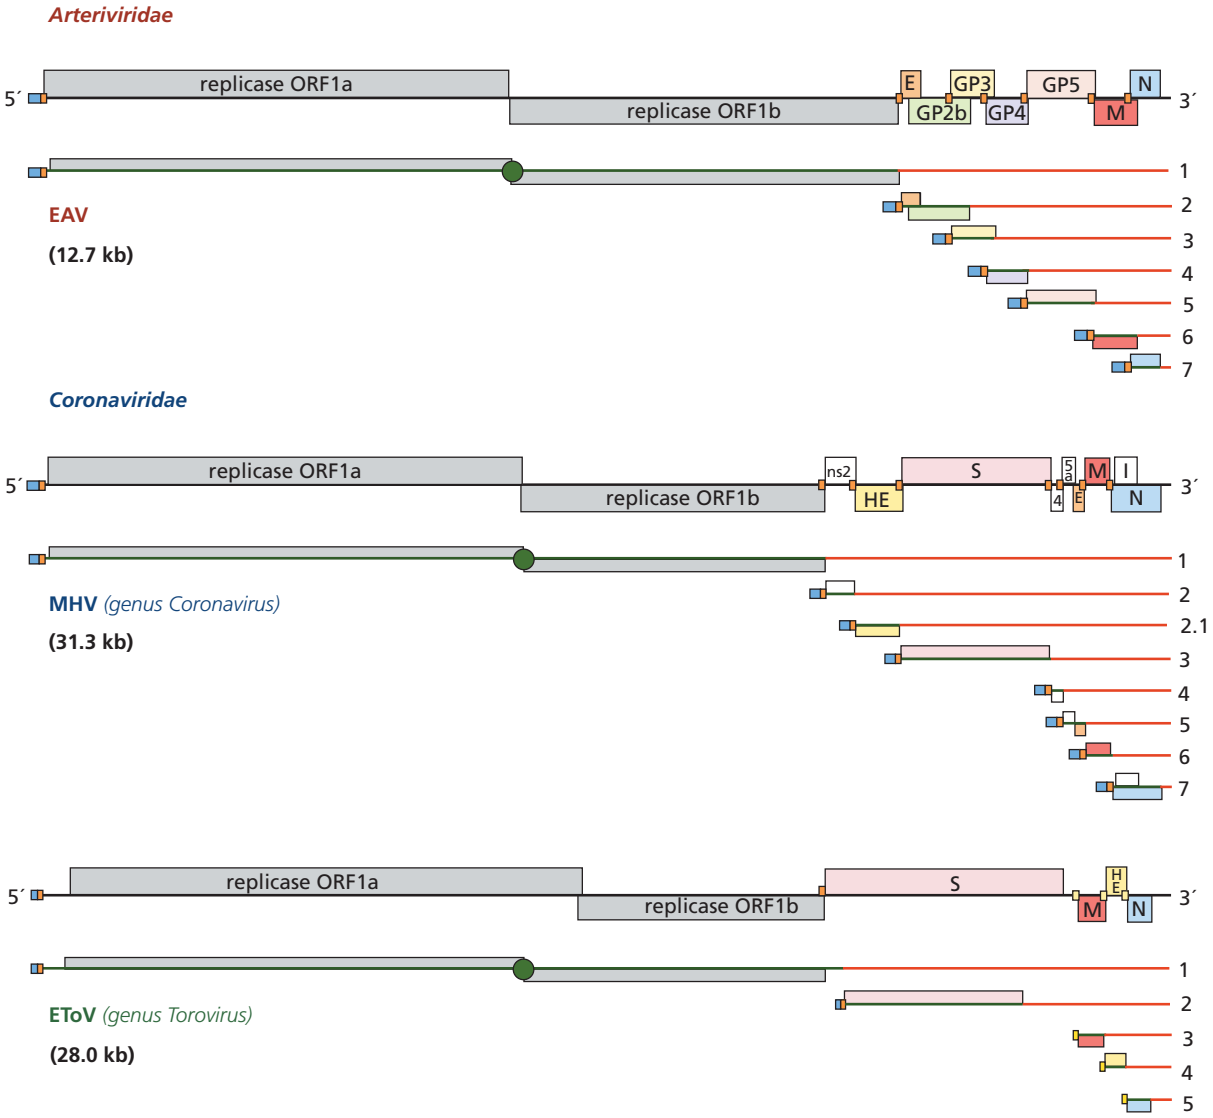

Figure 3 *The genome expression strategies of EAV, MHV, and EToV. The figure shows the genomic organization of the viruses and the structural relationships of the genome-length and subgenome-length mRNAs. The leader sequence and TRS sequences found at the 5′ end of EAV and MHV mRNAs, as well as the genome-length and subgenome-length mRNA2 of EToV are indicated as blue and orange boxes, respectively. The TRS-like element found at the 5′ end of EToV subgenome-length mRNAs 3, 4, and 5 is indicated as a yellow box. The ribosomal frameshifting element found in genome-length mRNA1 is indicated as a green circle and the translated region of each mRNA is indicated in green (the translationally silent regions are indicated in red). Only the translated ORFs are indicated for each mRNA.*

published literature and references therein (Alonso et al. 2002; Baric and Yount 2000; Curtis et al. 2004; Lai and Holmes 2001; Pasternak et al. 2001, 2004; Sawicki et al. 2001; Snijder and Meulenberg 2001; van der Most and Spaan 1995; van Vliet et al. 2002; Zuniga et al. 2004).

- The polycistronic genomic RNA of nidoviruses is infectious.
- Coronavirus and arterivirus subgenomic mRNAs are comprised of non-contiguous sequences. At their 5′ end they have a leader sequence of 65–100 nt (coronaviruses) or 150–210 nts (arteriviruses) that is derived from the 5′-proximal region of the genome. In toroviruses, only the largest subgenomic mRNA contains a short leader sequence derived from the 5′ end of the genome. All smaller torovirus subgenomic mRNAs do not contain this leader sequence.
- The site at which the leader and body of the mRNA are joined is defined by the position of a specific TRS, a conserved regulatory sequence preceding the mRNA body (body TRS). This sequence is also present at the 3′ end of the leader (leader TRS). The TRS is often referred to as the intergenic region or leader-body junction site in the older literature on coronaviruses and arteriviruses, respectively. In the case of all but the largest of the torovirus subgenomic mRNAs, the 5′ end of the mRNA is defined by a similar conserved regulatory sequence, apparently without the subsequent acquisition of the genomic 5′ leader sequence via a discontinuous RNA synthesis event as is found in coronaviruses and arteriviruses.
- The fusion of leader and body sequences of subgenomic mRNAs, as it occurs in coronaviruses and arteriviruses and the largest subgenomic mRNA of toroviruses, relies on a mechanism in which specific base-pairing interactions between RNA sequences and higher order RNA structures play an important role. This process appears to resemble sequence similarity-assisted RNA recombination, as it occurs in many positive strand RNA viruses (Nagy and Simon 1997).

In the coronaviruses:

- The bulk of the mRNA in the cell is produced from transcription intermediates that contain subgenome-length, negative-strand RNA. There is one transcription intermediate per mRNA species.
- The bulk of the subgenome-length negative-strand RNAs has an antileader sequence at their 3′ end.
- The subgenome-length RNAs (positive or negative strand) are not able to initiate a transcription complex.

It has also been shown that EAV-infected cells contain a set of subgenome-length transcription intermediates and that each intermediate contains a subgenome-length minus-strand RNA with an antileader sequence (den Boon et al. 1996).

These observations have been interpreted using two different models that essentially attempt to explain three basic questions. (1) How do subgenome-length templates arise? (2) How are the leader and body sequences of sg mRNAs joined? (3) What is the role of the conserved transcription-regulating sequences during subgenomic RNA synthesis?

The first model proposes that the genomic RNA enters the cell and is translated to produce RNA replicase that is used to synthesize a full-length negative-strand copy of the genome, the so-called antigenome. Transcription is initiated from the 3′ end of the antigenome and a leader transcript, identical to the 5′-proximal part of the genome, is synthesized. This leader RNA is then used to prime transcription of the different mRNA bodies, a process for which base pairing of the leader TRS (the TRS at the 3′ end of the leader RNA) with each of the body TRS complements in the antigenome would be a necessary interaction to synthesize a complete set of subgenomic mRNAs. The essential features of this model are that the discontinuous step takes place during positive-strand RNA synthesis and that the complement of each body TRS acts essentially as a promoter for subgenomic mRNA synthesis.

The second model has a different 'scenario.' Again, the genomic RNA enters the cell and is translated to produce RNA replicase. The RNA replicase is then used, however, to produce not only antigenome but also a set of subgenome-length negative-strand RNAs, the 3′ ends of which are defined by the body TRSs. These negative-strand RNAs then acquire an antileader sequence by a discontinuous 3′ terminal extension process that involves a crucial base pairing interaction between the body TRS complement at the 3′ end of the nascent minus strand and the leader TRS in the 5′ end of the genomic template (Pasternak et al. 2001; Zuniga et al. 2004). Subsequently, the subgenome-length negative-strand RNAs are completed by addition of the antileader sequence (the complement of the genomic leader sequence) and the subgenome-length minus-strand templates carry the RNA replicase into a transcription complex and act as templates for viral mRNA synthesis in the cell. In this model, discontinuous RNA synthesis takes place during the production of negative-strand RNA synthesis and the body TRSs act essentially as attenuators of RNA synthesis (Sawicki and Sawicki 1998).

Using the newly developed reverse genetics systems for arteriviruses (Meulenberg et al. 1998; van Dinten et al. 1997) and coronaviruses (Almazan et al. 2000; Thiel et al. 2001a; Yount et al. 2000), two important aspects of nidovirus discontinuous RNA synthesis were recently addressed (Pasternak et al. 2001; van Marle et al. 1999a; Zuniga et al. 2004). The first, which applies to both transcription models, is the base-pairing interaction between the leader TRS and the complement of the body TRS in the viral negative strand. By site-directed

mutagenesis, it was shown that disruption of this base-pairing interaction can dramatically affect subgenomic mRNA synthesis, whereas the introduction of compensatory mutations could restore subgenomic mRNA synthesis. The second aspect is the origin of the TRS that forms the leader-body junction in the mRNA molecule. Whereas the first model predicts this sequence to be a copy of the leader TRS, the discontinuous minus strand extension model predicts exactly the opposite, i.e. the sequence in the mRNA should be a copy of the body intergenic region or TRS. Using EAV TRS mutants with partial transcriptional activity, it was demonstrated that, indeed, the body TRS determines the sequence at the mRNA leader-body junction. Together with biochemical data obtained for coronaviruses (Baric and Yount 2000; Sawicki et al. 2001), these results provide strong evidence for the discontinuous minus strand extension model.

The remarkable recent data on the structure of torovirus subgenomic mRNAs (van Vliet et al. 2002), and the reported absence of a common 5′ leader sequence in roniviruses (see The order *Nidovirales*), have made it clear that the production of subgenomic RNAs by discontinuous RNA synthesis is not a universal feature of nidoviruses. The largest subgenomic mRNA of toroviruses is most likely generated in a manner similar to that proposed above for coronaviruses and arteriviruses. Namely, a short piece of identical sequence, present both at the 3′ end of the leader and the 5′ end of the body segment, functions as the cross-over site for an RNA recombination-like process during negative-strand RNA synthesis. This process may be enhanced by a predicted RNA hairpin located just upstream of the proposed attenuation site. However, for the remaining subgenomic RNAs of toroviruses, and for those of roniviruses, it was proposed that minus-strand synthesis is attenuated at the conserved ('TRS-like') sequence upstream of the body segment and that these attenuated minus-strand RNAs can function directly as templates for subgenomic mRNA synthesis. It is important that the minus-strands generated in cells infected with roniviruses and toroviruses are investigated in detail, to confirm that subgenome-length minus-strands indeed exist and result from attenuation of minus-strand RNA synthesis. However, if this is the case, it may be that the attenuation of minus strand RNA synthesis is, in fact, the common feature that unites the mechanisms used to produce subgenomic mRNAs in different nidoviruses. This conclusion would then provoke the question of the functions associated with the nidovirus leader sequence and, ultimately, the nature of the cis-acting signals needed for the promotion of nidovirus plus strand RNA synthesis. Finally, it should be noted that, in addition to the interactions described above, many other, as yet undiscovered, RNA–RNA, RNA–protein and protein–protein interactions are expected to play a role in nidovirus subgenomic mRNA synthesis (Pasternak et al. 2000; Shi et al. 2000; Tijms et al. 2001; van Dinten et al. 2000; Yu and Leibowitz 1995; Zhang and Lai 1995).

TRANSLATION

The production of a 3′ co-terminal set of subgenomic mRNAs in the infected cell allows for the expression of genes that are located internally on the nonsegmented genome. By and large, the viral mRNAs are thought to be functionally monocistronic although usually, with the exception of the smallest mRNA, they are structurally polycistronic. This conclusion is based mainly on the in vitro translation of coronavirus mRNAs and conforms to the conventional 'ribosome scanning' model of translational initiation. Thus, taking MHV as an example (Figure 3), the smallest mRNA, mRNA 7, encodes the nucleocapsid protein, mRNA 6 encodes the membrane protein, mRNA 3 encodes the spike protein, and so on. If the genomic sequence is known and the position of the functional body TRSs or intergenic regions has been determined by sequence analysis of mRNAs, a 'translational model' can be deduced for each of the viruses belonging to the order *Nidovirales*. It should be noted, however, that for arteriviruses, toroviruses, and even the majority of coronaviruses, this 'model' still needs to be confirmed by experiment.

The model outlined above describes the basic translational strategy of nidoviruses. However, Figure 3 indicates that there have to be exceptions. For example, MHV has no subgenomic mRNAs that could account for the expression of ORFs 1b, E, or I in this manner. It is now clear that nidoviruses also use a variety of alternative translation strategies to express some of their gene products.

In several coronaviruses (Brierley 1995; Brierley and Pennell 2001; Thiel et al. 2003), EToV (Snijder et al. 1990) and EAV (den Boon et al. 1991) the region of RNA that encompasses the overlap of ORFs 1a and 1b is able to mediate a high frequency of –1 ribosomal frameshifting. Thus, ORF1b is expressed as a fusion protein with the ORF1a gene product. As described above, ribosomal frameshifting is mediated by a 'shifty' sequence, the actual position at which frameshifting takes place, and an RNA pseudoknot which is believed to slow or halt the ribosome as it translates this sequence. The most likely mechanism of frameshifting is simultaneous slippage of two ribosome-bound tRNAs present in the aminoacyl and peptidyl sites of the ribosome during decoding of the 'shifty' sequence. The mechanistic aspects of nidovirus –1 ribosomal frameshifting have been analyzed in some detail (Brierley et al. 1997; Liphardt et al. 1999; Marczinke et al. 2000; Napthine et al. 1999).

The subgenomic mRNAs encoding the E proteins of MHV (mRNA 5) and IBV (mRNA 3) contain two and three ORFs, respectively, in their 5′ unique regions. The

E ORF is 3′-proximal in both cases and the mRNAs are functionally bi- and tricistronic, respectively (Budzilowicz and Weiss 1987; Liu et al. 1991). Therefore, the expression of the E ORF has to involve the internal initiation of protein synthesis. The unique region of both mRNAs contains an element that is able to mediate the internal entry of ribosomes and initiate protein synthesis in a cap-independent manner (Jendrach et al. 1999; Liu and Inglis 1992). This element has not yet been characterized in detail. A similar element has also been recognized in the mRNA 3 of certain TGEV strains (O'Connor and Brian 2000). In the arterivirus group, mRNA 2 of EAV was proposed to be a functionally bicistronic mRNA from which both the GP_{2b} glycoprotein and the newly discovered E protein are expressed (Snijder et al. 1999). Likewise, mRNA 2 of LDV and PRRSV and mRNA 4 of SHFV are probably used to express the corresponding genes of these other arteriviruses. Another mRNA of SHFV, mRNA 2, was proposed to be functionally bicistronic but, in this case, the expression of two ORFs (2a and 2b) from this mRNA remains to be demonstrated (Godeny et al. 1998).

Sequence analysis of the nucleocapsid protein gene of SARS-CoV, MHV, and related coronaviruses (Parker and Masters 1990; Snijder 2003a) has revealed an ORF, the internal or I ORF, which, in BCoV, is expressed in infected cells and encodes a 23-kDa, membrane-associated protein (Senanayake et al. 1992). The internal protein is translated from the same mRNA as the nucleocapsid protein, and it has been suggested, mainly on theoretical grounds, that the initiation of internal protein synthesis conforms to the 'leaky ribosomal scanning' model proposed by Kozak (Kozak 1999). Similar considerations apply to some of the small ORFs in the 3′-proximal region of the SARS-CoV genome (Snijder et al. 2003a).

Nonstructural polypeptides

REPLICASE

The replicase gene of viruses belonging to the order *Nidovirales* encodes two polyproteins of extraordinary size and complexity. The translation of ORF1a theoretically produces a polyprotein, pp1a, of 450–500 kDa (coronaviruses) or 190–260 kDa (arteriviruses). Alternatively, as described above, –1 ribosomal frameshifting is used to express an ORF1ab-encoded fusion protein, pp1ab, with a potential molecular weight of 750–800 kDa (coronaviruses) or 350–420 kDa (arteriviruses). Moreover, the polyproteins themselves are not the end products of replicase gene expression. Instead, they are co- and post-translationally cleaved by viral proteinases that are part of these polyproteins to produce a complex array of functional gene products.

Sequence analysis of the predicted nidovirus replicase polyproteins has revealed a number of putative functional domains that appear to have been conserved during evolution (Brown and Brierley 1995; de Vries et al. 1997; Gorbalenya 2001; Gorbalenya et al. 1989a; Snijder et al. 2003a; Snijder and Spaan 1995; Ziebuhr 2004a,b). These domains and their approximate positions are illustrated in Figur 4.

The ORF1a-encoded part of nidovirus pp1a and pp1ab polyproteins contains several proteinase domains, which are of two types. First, papainlike cysteine proteinase (PLpro) domains are located in the N-proximal half of the polyprotein. These may be single domains (SARS-CoV) or multiple domains (e.g. MHV and PRRSV). Nidovirus PLpro domains are generally linked with zinc-finger domains (Figure 4) (Snijder et al. 1995; Herold et al. 1999; Tijms et al. 2001) and have similar (sometimes overlapping) substrate specificities (Ziebuhr et al. 2001). At most PLpro cleavage sites, small aliphatic residues are conserved at the P1 and P1′ positions (Ziebuhr et al. 2000). Second, towards the C-terminal end of pp1a, a 3C-like proteinase domain (3CLpro) is found. In coronaviruses (and roniviruses), the active site nucleophile of this proteinase is a cysteine residue, whereas its arterivirus counterpart contains an active site serine (Hegyi et al. 2002; Liu and Brown 1995; Lu et al. 1995; Snijder et al. 1996; Ziebuhr et al. 1997, 2003). The 3CLpros of coronaviruses and arteriviruses are members of the large superfamily of chymotrypsin-like proteolytic enzymes that share a two-β-barrel fold (Gorbalenya et al. 1989b). There are significant structural differences between the coronavirus and arterivirus 3CLpros, for example, with respect to their sizes, subdomain organizations, and principal catalytic residues (Anand et al. 2002, 2003; Barrette-Ng et al. 2002). Despite these differences, the 3CLpros of coronaviruses and arteriviruses have similar substrate specificities (Hegyi and Ziebuhr 2002; Snijder et al. 1996; Thiel et al. 2003; Wassenaar et al. 1997; Ziebuhr et al. 1995, 2000). Thus, both enzymes cleave at sites that have a glutamine (coronaviruses) or glutamic acid (arteriviruses) at the P1 position and a small residue (usually glycine, alanine, or serine) at the P1′ position.

An important secondary function of pp1a appears to be the anchoring of the nidovirus replication complex to intracellular membranes (see below). Hydrophobic domains that flank the 3CLpro at either side are conserved in the pp1a proteins of all nidoviruses (Gorbalenya 2001; Snijder and Meulenberg 1998; Ziebuhr 2004a) (Figure 4). In the ORF1b-encoded product, which is expressed only as part of pp1ab, four domains have been conserved in all nidoviruses. The first is a RNA-dependent RNA polymerase module (RdRp) that is also found in a wide variety of putative RNA-dependent RNA polymerases. The alteration of the polymerase 'core' motif from glycine–aspartic acid–aspartic acid (GDD) to serine–aspartic acid–aspartic acid (SDD) is a feature that seems to be characteristic for the nidoviruses (Gorbalenya et al. 1989a). The second is a

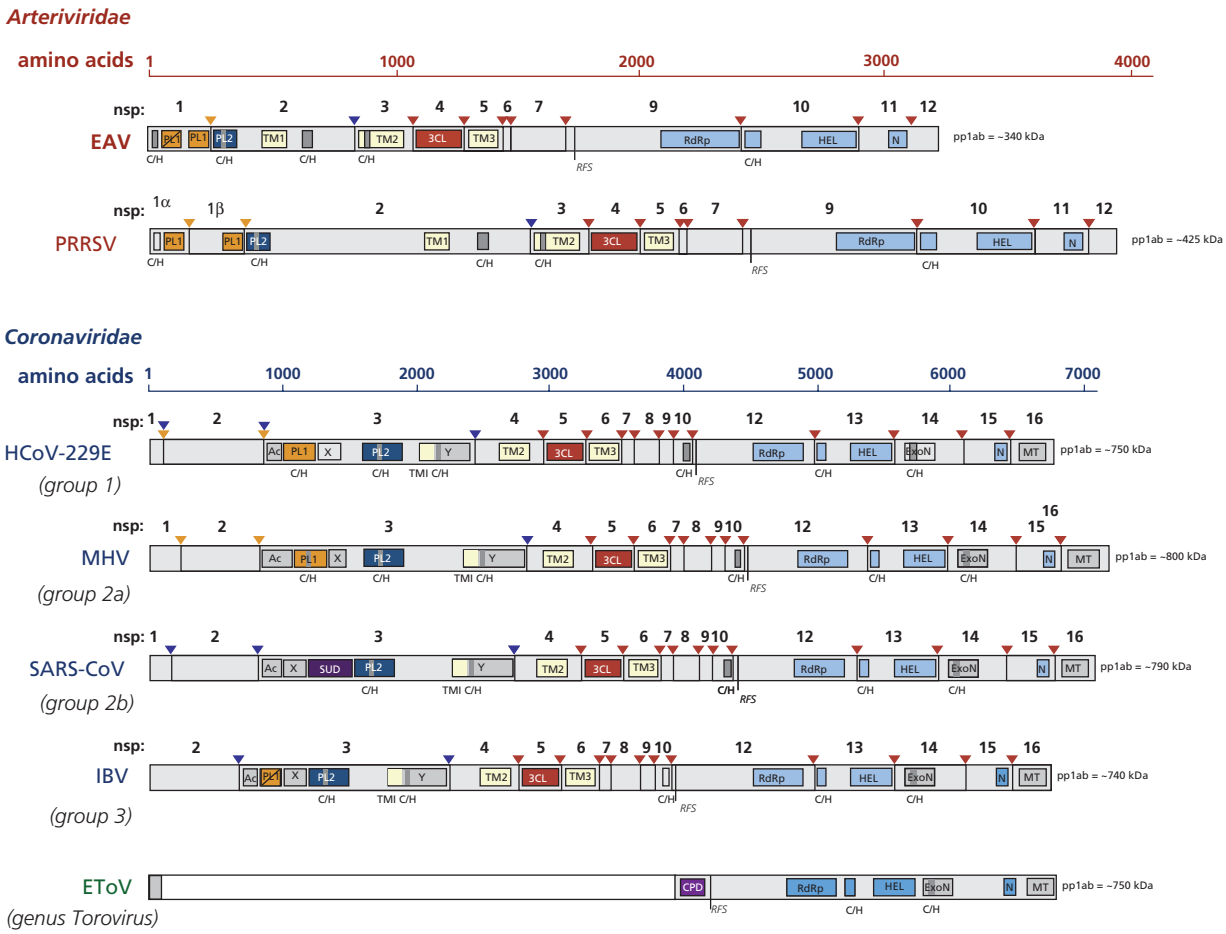

Figure 4 *The replicase gene organization of representative arteriviruses and coronaviruses. The replicase gene organization is depicted in the form of the polyprotein pp1ab. The delineation of amino acids encoded in ORF1a and ORF1b is indicated as RFS (ribosomal frameshift) and arrows represent sites in pp1ab that are cleaved by papainlike proteinases (orange and blue) or the main (3CL) proteinase (red). The proteolytic cleavage products are numbered and within the cleavage products, the location of domains that have been identified as structurally or functionally related are highlighted. These include domains with conserved Cys and His residues (C/H), putative transmembrane domains (TM), domains with conserved features (Ac, X, and Y), and domains that have been associated with proteolysis (PL1, PL2, and 3CL), RNA-dependent RNA synthesis (RdRp), helicase (HEL), exonuclease (ExoN), uridylate-specific endoribonuclease (N), and methyl transferase (MT) activities. Note that the arterivirus and coronavirus polyproteins are drawn to different scales.*

cysteine–histidine-rich motif that has been proposed to function as multinuclear zinc-finger (ZF) domain and was implicated in viral RNA synthesis (van Dinten et al. 1997, 2000). The third, and part of the same protein as the ZF domain, is a helicase domain. The location of the helicase domain downstream of the polymerase module in the polyprotein is unusual and characteristic of nidoviruses. And fourth is a conserved domain near the C-terminal end of pp1ab that was recently identified as a uridylate-specific endoribonuclease (NendoU) (Ivanov et al. 2004b; Snijder et al. 2003a). There are a number of (putative) additional RNA-processing activities (Snijder et al. 2003a) that appear to be differentially conserved among nidoviruses, indicating that the enzymology of viral RNA synthesis and/or some virus–host interactions may differ among the various nidovirus families and genera. Thus, for example, all nidoviruses (except for the arteriviruses) have been predicted to encode 3′-to-5′ exoribonuclease and 2′-*O*-ribose methyltransferase functions in ORF1b (Figure 4). Coronaviruses (but not arteriviruses and roniviruses) also encode a putative ADP-ribose 1″-phosphatase activity that is conserved in only very few plus-strand RNA viruses (Gorbalenya et al. 1991; Snijder et al. 2003a). Finally, toroviruses and group 2 coronaviruses (excluding SARS-CoV) encode a putative cyclic phosphodiesterase that is located at the C-terminus of the torovirus ORF1a encoded polyprotein, whereas the coronavirus homologue is expressed from a sg RNA (rather than being part of the replicase polyprotein itself) (Snijder et al. 2003a). The activities of most of the nidovirus RNA-processing enzymes remain to be characterized.

Compared with other positive-strand RNA viruses, the biochemical analysis of functions encoded in the

nidovirus replicase is still at an early stage (for a comprehensive review, see Ziebuhr (2004a)). There have been occasional reports of RNA-dependent RNA polymerase activity in subcellular fractions of coronavirus-infected cells or coronavirus-infected cells permeabilized with lysolecithin. However, there is no evidence that these systems can initiate RNA synthesis and their application has been very limited. Coronavirus RdRps and their nidovirus relatives have been classified as an outgroup of superfamiliy 1 RdRps (Koonin 1991). A molecular model for the coronavirus RdRp domain, which resides in the C-terminal two-thirds of nsp12 (Gorbalenya et al. 1989a) (Figure 4), has recently been reported (Xu et al. 2003). Furthermore, it has been proposed that the MHV nsp12 interacts through a protein segment located upstream of the C-terminal RdRp core domain with ORF1a-encoded proteins, such as nsp4 ($3CL^{pro}$), nsp8, and nsp9 (Brockway et al. 2003). Crystal structure analysis of SARS-CoV nsp9 and biochemical data have shown that nsp9 is a single-stranded RNA-binding protein (Egloff et al. 2004; Sutton et al. 2004) and genetic data obtained for MHV have implicated nsp10 in minus-strand synthesis (Siddell et al. 2001). Taken together, the data suggest that the small proteins encoded by the 3′-proximal region of ORF1a may have co-factor functions for the RdRp and be directly or indirectly involved in viral RNA synthesis.

In the replicase polyprotein, the RdRp domain is C-terminally flanked by a multidomain protein, called nsp10 in arteriviruses and nsp13 in coronaviruses, which contains N-terminal ZF and C-terminal helicase domains (Figure 4). Nidovirus helicases have been shown to have NTPase, RNA 5′-triphosphatase as well as RNA and DNA duplex-unwinding activities (Bautista et al. 2002; Heusipp et al. 1997; Ivanov et al. 2004a; Ivanov and Ziebuhr 2004; Seybert et al. 2000a, 2005; Tanner et al. 2003). Coronavirus and arterivirus helicases appear to act processively and unwind their substrates with 5′-to-3′ polarity (Ivanov et al. 2004a; Ivanov and Ziebuhr 2004; Seybert et al. 2000a, 2005). The N-terminal ZF was recently shown to be required for the enzymatic activities of nidovirus helicases (Seybert et al. 2005). Both the in vitro activities of nsp10/nsp13 and RNA replication of EAV in tissue culture were found to be extremely sensitive to substitutions of conserved Cys and His residues in the ZF domain (Seybert et al. 2005; van Dinten et al. 2000). Furthermore, point mutations that selectively inactivate EAV sg RNA synthesis (van Dinten et al. 1997, 2000; van Marle et al. 1999b) were identified and mapped to the region connecting the ZF and helicase domains of the protein. The flexibility of this spacer was postulated to be essential for the function of the protein in sg RNA synthesis. Furthermore, the most N-terminal cleavage product of the EAV replicase, nsp1, was implicated in the regulation of sg RNA synthesis. The protein was shown to be dispensable for genome replication, but absolutely required for sg RNA synthesis (Tijms et al. 2001).

Recently, manganese-dependent, uridylate-specific endoribonuclease activities (NendoU) were established for nsp15 of SARS-CoV and HCoV-229E (Ivanov et al. 2004b; Snijder et al. 2003a; Bhardwaj et al. 2004) (Figure 4). The nsp15 activity was shown to be critically involved in coronavirus RNA synthesis. Although nsp15 is capable of cleaving both single-stranded and double-stranded RNA in vitro, the biologically relevant substrate was proposed to be double-stranded RNA, which is cleaved more effectively and specifically at GU and GUU sequences (Ivanov et al. 2004b). 2′-*O*-ribose-methylated RNA substrates proved to be resistant to cleavage by nsp15, indicating that the putative 2′-*O*-ribose methyltransferase domain residing adjacent to NendoU in the coronavirus replicase polyprotein may control or modulate the ribonucleolytic activity of nsp15.

Also, there are an ever-increasing number of reports on the characterization of arterivirus and coronavirus proteinases and the proteolytic processing of the replicase gene products. A detailed review of these data is beyond the scope of this chapter (for recent reviews, see Ziebuhr 2004a; Ziebuhr et al. 2000). Briefly, the papain-like proteinases seem to be largely responsible for the processing in *cis* of N-terminal and N-proximal products from the ORF1a-encoded region of the replicase polyproteins, whilst the 3C-like proteinases are likely to function mainly in *trans* and are responsible for self-excision and processing of the pp1a and pp1ab polyproteins downstream of the proteinase domain itself (Figure 4). Because of their key role in polyprotein processing, nidovirus 3C-like proteinases are considered to be attractive targets for antiviral (in particular, anti-SARS) drug development (Anand et al. 2003; Davidson and Siddell 2003). Over the past years, significant progress has been made in the functional and structural characterization of these enzymes. Thus, for example, crystal structures of several coronavirus and arterivirus 3C-like proteinases have been reported and the binding modes of proteinase substrates have been elucidated by X-ray structure analysis of inhibitors bound to the active sites of TGEV and SARS-CoV 3CLpros, respectively (Anand et al. 2002, 2003; Barrette-Ng et al. 2002; Shi et al. 2004; Yang et al. 2003). The structural information provides an excellent basis for rational drug design and, because of the conserved substrate specificity of coronavirus 3CLpros, even the development of broad-spectrum proteinase inhibitors suitable for the therapy of human and animal coronavirus infections may be a tractable goal (Anand et al. 2003; Hegyi and Ziebuhr 2002; Thiel et al. 2003). Also, other nidovirus replicative proteins, such as the RNA-processing enzymes, RNA-binding proteins, RdRp, and the helicase, might be targets for selective antiviral therapies (Davidson and Siddell 2003), although their characterization is still at an early stage.

INTRACELLULAR LOCALIZATION OF THE REPLICASE

Over the past decade, the association of their replication complex with intracellular membranes (of different origin) has emerged as a common feature of positive-strand RNA viruses that replicate in eukaryotic cells (see, for example, Ahlquist et al. 2003; Mackenzie et al. 1999; Rust et al. 2001; Salonen et al. 2003) and references therein). The association of viral replicases with (modified) cellular membranes is thought to be an important advantage in creating a suitable (micro)-environment for viral RNA synthesis. Furthermore, the formation of membrane-bounded complexes may aid in shielding double-stranded RNA replication intermediates from double-stranded RNA activated host defense mechanisms such as RNA interference and interferon-induced pathways.

The subcellular localization of the replicase has only been studied in detail for the arterivirus EAV and for the coronavirus MHV. In the case of EAV, most replicase subunits (including RdRp and helicase) localize to virus-induced double-membrane structures that are likely derived from the endoplasmic reticulum (ER) (Pedersen et al. 1999; van der Meer et al. 1998). These paired membranes and double membrane vesicles (DMV) were shown previously to be induced by arterivirus infection. DMVs that strikingly resemble those seen in virus-infected cells could also be induced by expressing a part of the EAV pp1a protein (nsp2 and nsp3) (Pedersen et al. 1999; Snijder et al. 2001), indicating that their generation does not depend on viral replication or the presence of ORF1b-encoded protein functions. All cleavage products of the EAV pp1a and pp1ab polyproteins (with the exception of a fraction of nsp1; Tijms et al. 2002) and de novo synthesized RNA (as visualized by BrUTP labeling) colocalize to membranes in the perinuclear region of infected cells (Pedersen et al. 1999; van der Meer et al. 1998). Also, a substantial proportion of the EAV nucleocapsid protein was found in this region of the cell, but its involvement in genome replication or subgenomic (sg) RNA synthesis is highly unlikely, since nucleocapsid gene expression can be inactivated without a significant effect on either process (Molenkamp et al. 2000; Tijms et al. 2002).

For the only coronavirus studied in some detail thus far, MHV, the situation is less clear-cut, which may be partially due to the use of (i) a variety of cell lines, (ii) different cellular marker proteins, and (iii) antisera recognizing different MHV replicase subunits (compare, for example, Bost et al. 2001; Denison et al. 1999; Gosert et al. 2002; Shi et al. 1999, van der Meer et al. 1998). The majority of the MHV replicase subunits were found to be associated with intracellular membranes. During the peak of MHV RNA synthesis, key nonstructural proteins, like RdRp and helicase, de novo synthesized RNA, and also the viral nucleocapsid protein, were found to colocalize in punctate cytoplasmic foci (Denison et al. 1999; Shi et al. 1999; van der Meer et al. 1998). Ultrastructural studies of the replicase complex in MHV-infected cells have remained equivocal thus far. While the results of one study pointed mainly to membranes of (late) endosomal origin as the site of viral replication (van der Meer et al. 1998), a more recent study (Gosert et al. 2002) identified virus-induced double-membrane structures, resembling those implicated in the RNA synthesis of arteriviruses. Although all reports support the membrane association of MHV (and more recently also SARS-CoV) RNA synthesis, a variety of different cellular compartments (including ER, Golgi complex, endosomes, and autophagosomes) have been implicated in viral RNA synthesis (Ivanov et al. 2004a; Prentice et al. 2004a,b). Furthermore, the localization of, in particular, the MHV helicase protein, was reported to change later in infection (Bost et al. 2001).

Although further studies are necessary before definite conclusions can be reached, it does appear that major differences between arterivirus and coronavirus replication complexes may exist. In general, it is unclear how the nidovirus replicase associates with membranes. The most relevant questions are: (i) the mechanism of membrane insertion of the replicase subunits that anchor the complex, (ii) the coordination of proteolytic processing and membrane association, (iii) the role of protein–protein interaction (between viral proteins and possibly between viral and host proteins), and (iv) the interaction with host membranes, including the formation of double membranes and DMVs.

ACCESSORY PROTEINS

In the case of the arterivirus EAV, it has been shown that none of the ORFs downstream of the replicase gene are required for genome replication or subgenomic (sg) mRNA synthesis (Molenkamp et al. 2000). Each of these genes seems to encode a structural protein that is essential for the production of infectious progeny virus (Wieringa et al. 2003a). In the case of coronaviruses, there are a variety of proteins of unknown function encoded downstream of the replicase gene. Little more is known about them than their predicted molecular weights and putative structural features deduced from computer-assisted analyses (Brown and Brierley 1995) (see Figure 4). They do not appear to be essential for coronavirus sg RNA synthesis (Thiel et al. 2001b). The expression of some of the accessory proteins has been confirmed in coronavirus-infected tissue culture cells (reviewed in Brown and Brierley 1995) and evidence of post-translational modification (e.g. phosphorylation of the BCoV ORF2 protein) (Cox et al. 1991) has been obtained. Recently, the crystal structure of the SARSCoV ORF7a protein revealed an Ig-like fold for this intracellular membrane protein (Nelson et al. 2005). The picture, however, remains very incomplete. Despite

this lack of information, two interesting observations have been made. First, for some coronaviruses, variants have been obtained that are defective for the expression of one or more of these proteins but are able, nevertheless, to replicate normally in tissue culture. Thus, for example, MHV variants defective for the expression of the ORF2, ORF4 or ORF5a gene products have normal properties in vitro (Schwarz et al. 1990; Yokomori and Lai 1991). Consistent with this idea, other studies show that deletion of the accessory genes from the MHV or FIPV genomes, result in replication-competent viruses that are, nevertheless, attenuated in mice and cats respectively, suggesting that these proteins provide a selective advantage in the natural host (de Haan et al. 2002b; Haijema et al. 2004). Second, it seems that the functions carried by some proteins of the *Coronaviridae* may be looked upon as 'genetic cassettes.' Thus, for example, the MHV CPDase domain is encoded by ORF2 whereas its EToV homologue is encoded at the 3′ end of the ORF1a (Snijder et al. 1991). Another example of this concept is the proteins encoded by ORFs 4a and 4b of HCoV-229E, which seem to be equivalent to the single protein encoded by ORF3 of porcine epidemic diarrhoea virus (PEDV) (Duarte et al. 1994). In a similar vein, SARS-CoV has been predicted to encode as many as eight accessory proteins. Also in this case, it seems that (at least some of) these proteins are not essential in tissue culture. Thus, for example, a deletion in ORF7b was observed upon passage of the Frankfurt 1 strain of SARS-CoV in tissue culture (Thiel et al. 2003). Furthermore, SARS-CoV isolates obtained from SARS patients differed from SARS-CoV-like viruses isolated from Himalayan palm civets (and one human isolate, GZ01) by a 29-nucleotide deletion in ORF8 (Guan et al. 2003), generating two smaller ORFs, 8a and 8b. The biological significance of the deletion (e.g. in terms of pathogenesis and/or adaptation to the human host) remains to be investigated. Thus far, only one of the SARS-CoV accessory proteins, the ORF3a protein, has been characterized in some detail (Yu et al. 2004; Zeng et al. 2004). Sequence comparison of diverse SARS-CoV isolates suggests a correlation of specific substitutions in the ORF3a and spike protein genes, suggesting that the biological function of the ORF3a protein is closely associated with spike protein functions (Zeng et al. 2004). The study suggests that the ORF3a protein associates with the SARS-CoV spike protein by intermolecular disulfide bridges and it is proposed that the ORF3a protein may be an additional structural protein.

Structural polypeptides

Whereas the RNA replicase provides clear evidence of an evolutionary link between viruses of the order *Nidovirales*, the structural proteins indicate a complex phylogeny, probably involving both recombination and evolution from a common ancestor. For example, the nucleoproteins of corona-, toro-, and arteriviruses show no sign of any relationship (apart from the features common to almost all nucleoproteins) whilst the envelope proteins of coronaviruses and toroviruses are clearly related both structurally and functionally. The structural proteins of coronaviruses, toroviruses, and arteriviruses are listed in Table 2.

NUCLEOCAPSID AND MEMBRANE POLYPEPTIDES

The nucleoprotein of corona-, toro-, and arteriviruses is a basic phosphoprotein that associates with the genomic RNA to form the nucleocapsid structure. However, the

Table 2 *Structural proteins of corona-, toro-, and arteriviruses*

Protein		Molecular weight (kDa)			Glycosylation	Abundance	Comments
		Corona	Toro-	Arteri-			
Nucleoprotein	N	50–69	19	12	No	Major	Basic, phosphorylated
Membrane	M	23–35	27	16	Only coronavirus	Major	Multi-membrane-spanning protein
Spike	S	180–220	200	...[a]	Yes	Major	Peplomer structure with coiled-coil elements
Envelope	E	9–12	...	7–9	No	Minor	Integral membrane protein
Hemagglutinin esterase	HE	65	65	...	Yes	Major	Subset of coronaviruses, disulfide-linked homodimer
Glycoprotein	GP_2	...	...	23–28	Yes	Minor	Part of $GP_2/Gp_3/GP_4$ heterotrimer
Glycoprotein	GP_3	...	...	18–29	Yes	Minor	Part of $GP_2/Gp_3/GP_4$ heterotrimer
Glycoprotein	GP_4	...	...	16–20	Yes	Minor	Part of $GP_2/Gp_3/GP_4$ heterotrimer
Glycoprotein	GP_5	...	...	30–45	Yes	Major	Disulfide-linked heterodimers with M

a) No such protein described.

nature of this association must be very different for the three groups of viruses. First, the sizes of the nucleocapsid proteins differ markedly and, secondly, the three groups of virus structures have very different morphologies. In a relaxed configuration, the coronaviruses and toroviruses have a helical nucleocapsid, which is unique among positive-strand RNA enveloped viruses, whilst the arteriviruses have an isometric (cubical) nucleocapsid. Recent data suggests that the coronavirus nucleocapsid protein binds to RNA with little sequence specificity (Narayanan et al. 2003a). Sequence comparisons and some partial structural information on coronavirus and arterivirus nucleocapsid proteins suggest a multidomain structure (Huang et al. 2004; Laude and Masters 1995), but the specific functions of the various domains remain to be elucidated. The partial crystal structure of the PRRSV N protein suggests that it may represent a new class of capsid-forming protein, with domains distinctly different from those of other known enveloped viruses (Doan and Dokland 2003). Both coronavirus and arterivirus nucleocapsid proteins assemble into higher order structures in virus-infected cells and when expressed as recombinant proteins (He et al. 2004; Narayanan et al. 2003b; Surjit et al. 2004; Wootton and Yoo 2003). Also, it has been noted that both the coronavirus and arterivirus nucleocapsid proteins have nucleo-nucleolar transport signals and a fraction of the protein synthesized in infected cells localizes to the nucleolus (Hiscox et al. 2001; Rowland et al. 2003; Tijms et al. 2002). However, it is not clear if this phenotype is linked, for example, to the viral modulation of nucleolar function, or simply a case of fortuitous molecular mimicry.

Coronaviruses and arteriviruses both have a multi-membrane-spanning protein, M. For most M proteins, it is thought that one of the hydrophobic transmembrane domains functions as an internal signal sequence, although for the M proteins of TGEV, FCoV, and CCoV an amino terminal signal sequence is present. Transient expression studies have revealed that the M protein also carries a signal for retention in the Golgi apparatus (coronavirus) or endoplasmic reticulum (torovirus and arterivirus) of the cell. Only when it is associated with other components of the virion does the M protein proceed beyond these compartments. Despite the striking similarities in structure of coronavirus and arterivirus M proteins, there are also significant differences. For example, only the M proteins of coronaviruses are glycosylated. In BCoV, MHV, and HCoV-OC43, *O*-glycosylation has been demonstrated; for the other coronaviruses, *N*-glycosylation is found (de Haan et al. 2002a; Rottier 1995).

Recent studies have shed some light on the role of the M protein in coronavirus budding. It appears that the coronavirus M protein may exist in two conformations. In TGEV, approximately two-thirds of the molecules are triple-membrane spanning and have a N_{exo}-C_{endo} configuration: the remaining molecules are quadruple-membrane spanning and have a N_{exo}-C_{exo} configuration. The molecules with an intravirion carboxyl-terminus are thought to interact with the nucleocapsid structure (Escors et al. 2001). Consistent with this conclusion, studies on MHV have suggested that the M protein interacts with the nucleocapsid structure, either by an M protein–N protein interaction (Kuo and Masters 2002) or by specifically binding to the packaging signal in the genomic RNA (Narayanan et al. 2003a). In any case, the M protein would link the incorporation of nucleocapsid structures to the virus budding process. Finally, de Haan and colleagues have shown that there are strong homotypic interactions between MHV M proteins and they suggest that these lateral interactions within the viral membrane generate the major driving force for envelope formation (de Haan et al. 1998, 2000). As discussed below, the coronavirus M protein is also believed to interact with the spike glycoprotein. Very little is known about the functional role(s) of the arterivirus M protein. It has been shown that the EAV and LDV M and GP_5 proteins are associated in virus particles as disulfide-linked heterodimers and that covalent linkage is essential for virus infectivity (Snijder et al. 2003b).

The coronavirus envelope protein, E, is predicted to have a hydrophobic region, located in the amino terminal half of the polypeptide, which is flanked by charged residues. Adjacent to this hydrophobic domain is a cysteine-rich region, followed by an abundance of charged residues in the carboxy half of the polypeptide (Siddell 1995). These features are indicative of an integral membrane protein, and a membrane location for the E proteins of IBV, TGEV, and MHV virions has been demonstrated. Recently, a cation-selective ion channel function has been demonstrated for the SARSCoV E protein (Wilson et al. 2004). The E protein, together with the M protein, has been shown to facilitate coronavirus particle formation (Bos et al. 1996; Fischer et al. 1998; Vennema et al. 1996) and recent data has shown that the E protein accumulates in and induces curvature into the pre-Golgi membranes where coronaviruses assemble by budding (Arbely et al. 2004; Raamsman et al. 2000). Although there is clear evidence for the importance of the E protein in the assembly of coronaviruses, it is not absolutely essential (Kuo and Masters 2003). The E protein is also reported to induce apoptosis (An et al. 1999). The identification of the E protein of arteriviruses has further extended the collection of structural proteins of this virus group (Snijder et al. 1999; Wu et al. 2001). The hydropathy profile of this small hydrophobic non-glycosylated protein suggests that it is an integral membrane protein with an uncleaved signal-anchor sequence in the central part of the molecule.

MAJOR GLYCOPROTEINS

The coronavirus and torovirus spike glycoproteins have a number of features in common: a large number (18–35) of potential *N*-glycosylation sites, an N-terminal

signal sequence, a C-terminal transmembrane anchor domain, putative heptad repeat domains and, with the exception of some coronaviruses (e.g. TGEV, FCoV, SARSCoV, and HCoV-229E), a centrally located, arginine-rich cleavage site for a 'trypsinlike' proteinase. When post-translational cleavage takes place (which varies according to the virus and the cell) the quaternary structure of the protein is an oligomer (dimer or trimer), each monomer being comprised of two subunits, S1 (amino terminal) and S2 (carboxyl terminal) that are noncovalently linked. The S1 subunit is thought to be a globular protein that comprises the bulbous head of the peplomer. The heptad repeat domains, which are located in the S2 subunit, are thought to generate intrachain coiled-coil secondary structure (more precisely, antiparallel six helix bundles) and provide the stalk of the peplomer with its rigid, elongated structure (Cavanagh 1995). More detailed structural analysis of the coronavirus spike protein fusion core suggests that it shares significant similarity with both the low pH-induced conformation of influenza hemagglutinin and the fusion core of human immunodeficiency virus (HIV) gp41 (Bosch et al. 2003; Ingallinella et al. 2004; Tripet et al. 2004; Liu et al. 2004; Xu et al. 2004a, b). This suggests that the mechanisms for the viral fusion of coronaviruses might be quite similar to those of other class I virus fusion proteins. The MHV S protein is acylated, and it has been speculated that fatty acid chains are associated with a cluster of cysteine residues located in the C-terminal, hydrophilic tail of the protein. The same region has been implicated in spike protein-mediated membrane fusion (Chang et al. 2000; Ye et al. 2004). Finally, the assembly of the coronavirus spike protein into virions involves an interaction between the charge-rich carboxyl-terminal region of the endodomain, most probably with the membrane protein (de Haan et al. 1999).

The spike protein of coronaviruses has at least two major functions in virus replication. First, it binds to cellular receptors to initiate the infection process. The S protein–receptor interaction is complex and may involve the recognition of carbohydrates as well as protein. However, the major class of protein receptor for MHV has been identified as isoforms of the Bgp glycoprotein, a group of murine, carcinoembryonic antigen (CEA)-related glycoproteins in the biliary glycoprotein subgroup (Dveksler et al. 1993; Hemmila et al. 2004). Similarly, the metalloproteinase, aminopeptidase N (also called CD13 in humans) has been identified as the protein receptor for TGEV and HCoV-229E (Delmas et al. 1992; Yeager et al. 1992). Finally, angiotensin-converting enzyme 2 (ACE2) has been identified as a functional receptor for the SARS-CoV (Li et al. 2003; To and Lo 2004). It seems clear that the coronavirus spike protein is a major determinant of cell and species tropism (Casais et al. 2003; Haijema et al. 2003). The second major function of the S protein is to mediate membrane fusion. This activity is necessary for the fusion of viral and cellular membranes at the cell surface during the initial stages of infection, and it may also occur later in infection by extensive formation of syncytia. In the coronaviruses, virus entry is thought to take place at the cell surface or within endosomes prior to their acidification. However, mutants of MHV that depend on low pH for fusion activity have been isolated (Gallagher et al. 1991) and SARS-CoV S-pseudotyped lentiviral vectors also display pH-dependent fusion (Yang et al. 2004a). Cleavage of the S protein seems to enhance its cell-to-cell fusion activity but is not required for virus infectivity (de Haan et al. 2004; Gombold et al. 1993). Bosch and colleagues have recently identified a putative fusion peptide in the S protein of a number of coronaviruses (Bosch et al. 2004).

The arterivirus major glycoprotein, GP_5 is sometimes considered as 'equivalent' to the coronavirus S protein but its structure is completely different and it appears to lack some of the important biological functions ascribed to the coronavirus spike glycoprotein. Recent analyses suggest that it is a polytopic class I protein; after removal of the signal peptide, the processed protein consists of an N terminal ectodomain (about 30 amino acids for LDV and PRRSV, 95 amino acids for EAV) which is *N*-glycosylated, an internal hydrophobic region that crosses the membrane three times and a C-terminal endodomain of 50–75 amino acids (Snijder et al. 2003b). The ectodomain of the EAV GP_5 protein carries one or two polylactosaminoglycans, a very unusual modification for a viral glycoprotein. The corresponding LDV protein was shown to carry 1–3 polylactoaminoglycans that strongly influence immunogenicity, sensitivity to antibody neutralization and neuropathogenicity (Li et al. 1998). At the present time, there is only limited information on the functions that are likely to be associated with this protein. The PRRSV GP_5–M protein hetrodimer has been implicated in attachment to a heparin-like receptor on the surface of porcine alveolar macrophages (Delputte et al. 2002) but studies with EAV chimeras make it clear that a factor other than the GP_5 ectodomain may determine the host specificity of arteriviruses (Dobbe et al. 2001). Likewise, the tropism of PRRSV M protein mutants carrying the ectodomain of other arteriviruses was unchanged, indicating that both ectodomains in the GP_5–M heterodimer can be replaced without a detectable effect on cell tropism (Verheije et al. 2002a). Recently, it has been shown that porcine sialoadhesin mediates the internalization of PRRSV into alveolar macrophages and that the presence of sialic acid on the virus is essential for attachment (Delputte and Nauwynck 2004; Vanderheijden et al. 2003).

The hemagglutinin-esterase glycoprotein is a structural protein that is restricted to a subset of the *Coronaviridae*. A strong hemagglutinating property and a second, shorter, fringe of peplomers on the virion surface characterize this subset, which includes HEV, BCoV, MHV, HCoV-OC43, and TCoV (Brian et al.

1995). Amongst the toroviruses, BToV has been shown to express a hemagglutinin-esterase protein (Cornelissen et al. 1997). It should be noted that some other coronaviruses (for example, TGEV and IBV) can also display strong hemagglutinating activity but this is a property of the surface glycoprotein S and is usually cryptic: treatment of the virus with, for example, neuraminidase is required to 'activate' hemagglutination. Finally, even for hemagglutinating coronaviruses, variants have been found that, for one reason or another, have lost the ability to express a functional HE protein. Thus, for example, the MHV strain A59 is defective in this respect. In the same way, it seems likely that the single isolate of EToV studied to date, which clearly carries the remnants of an HE protein gene but does not express an HE protein, is also a variant virus.

In the case of MHV, the HE protein is a disulfide-linked homodimer. The monomer polypeptide (65–75 kDa) has an N_{exo}–C_{endo} configuration and is *N*-glycosylated in the ectodomain. Transient expression of the MHV and BCoV HE proteins has shown that the protein has both hemagglutinin and esterase activities (Pfleiderer et al. 1991; Yoo et al. 1992). The acetylesterase activity of BCoV is specific for *N*-acetyl-9-*O*-neuraminic acid (Vlasak et al. 1988). Comparison of the coronavirus HE protein sequence and the sequence of the influenza C virus HEF protein reveals a remarkable degree of conservation, including, for example, many cysteine residues and the active site motif 'phenyalanine–glycine–aspartic acid–serine–arginine' (FGDSR) (Vlasak et al. 1988). It has been speculated that the *HE* gene of coronaviruses has been acquired by an RNA recombination event between ancestral nidoviruses and influenza C viruses (Luytjes et al. 1988; Snijder et al. 1991).

The importance of the coronavirus HE protein is not yet clear. On the one hand, there is evidence for a functional role: for example, monoclonal antibodies specific for the BCoV HE protein are able to neutralize virus infectivity. On the other hand, MHV A59, which does not have an HE protein, is able to replicate quite normally in tissue culture. Moreover, it has been shown that, even for coronaviruses that express high levels of HE, the HE–ligand interaction alone is not sufficient to mediate infection (Gagneten et al. 1995; Popova and Zhang 2002). One possibility is that the interaction of HE with *N*-acetyl-9-*O*-neuraminic acid serves to concentrate virus on the cell membrane and thereby facilitates the interaction of the coronavirus S protein with its specific protein receptor molecule. As the levels of cell surface *N*-acetyl-9-*O*-neuraminic acid can differ dramatically in vivo, this interaction may still be an important determinant of pathogenicity.

MINOR GLYCOPROTEINS

The minor arterivirus glycoprotein encoded by ORF2b (GP_{2b}; EAV/LDV) or ORF2a (GP_{2a}; PRRSV) is a conventional class I integral membrane protein with an N-terminal signal peptide, a C-terminal transmembrane segment, and 1–4 potential *N*-glycosylation sites. The protein is significantly under-represented in EAV particles (at least in relation to its intracellular abundance) (de Vries et al. 1992) and was shown to occur in EAV-infected cells in a variety of monomeric conformations and complexed with other minor glycoproteins (de Vries et al. 1995; Wieringa et al. 2003a). Complex formation is a prerequisite for GP_{2b} incorporation into virions, although the equivalent PRRSV protein was reported to be present in virions as a monomer (Meulenberg and Petersen-den Besten 1996). Recent mutagenesis studies using an EAV infectious cDNA clone revealed that cysteine residues in the GP_{2b} ectodomain form both intramolecular and intermolecular cysteine bridges, the latter involving a cysteine of the GP_4 ectodomain (Wieringa et al. 2003b).

The PRRSV and EAV GP_4 proteins were also identified as minor glycoprotein constituents of the virus particle (van Nieuwstadt et al. 1996; Wieringa et al. 2002). They contain an N-terminal signal sequence, a C-terminal membrane anchor and a small endodomain, which are typical properties of class I integral membrane proteins.

The EAV GP_3 protein is a heavily glycosylated integral membrane protein with an uncleaved N-terminal signal sequence and a hydrophobic C-terminal domain. The protein is inserted into the lipid bilayer by either or both of its hydrophobic termini and has no detectable endodomain (Hedges et al. 1999; Wieringa et al. 2002). Like GP_{2b} and GP_4, EAV GP_3 localizes to the endoplasmic reticulum, both in infected cells and in expression systems (Wieringa et al. 2002). There is no doubt about the presence of GP_3 in EAV particles (Wieringa et al. 2002), but conflicting data on the presence of PRRSV GP_3 in virions have been reported. Whereas GP_3 was detected in purified European PRRSV by using specific monoclonal antibodies (van Nieuwstadt et al. 1996), the protein could not be immunoprecipitated from a purified virus preparation of a North American isolate (Mardassi et al. 1998). However, small amounts of the latter protein were detected in a soluble form in the medium. Topological studies on the corresponding LDV protein also suggested it to be a secretory protein but, thus far, this protein could not be detected in cell lysates or the medium of infected cells (Faaberg and Plagemann 1997).

Recent studies on the GP_{2b}, GP_3, and GP_4 proteins of EAV have revealed various important properties of the arterivirus minor glycoproteins. By separately knocking out the expression of each of the EAV structural proteins in the context of a full-length EAV cDNA clone, it was shown that both major and minor structural proteins are required for the production of infectious progeny virus (Molenkamp et al. 2000). Subsequently, it was found that knock-out mutants for minor structural protein expression produce noninfectious subviral particles consisting of GP_5, M, N, and the viral RNA genome (Wieringa et al. 2004; Zevenhoven-Dobbe et al. 2004). These subviral particles did not differ from wild-type

virus in terms of buoyant density, major structural protein composition, and appearance in electron microscopy. When one of the proteins GP_{2b}, GP_3, or GP_4 was missing, the incorporation of the other minor GPs was blocked and that of the E protein was greatly reduced (Wieringa et al. 2004). The absence of the E protein completely blocked the incorporation into virions of the three minor glycoproteins, which are present in equimolar amounts and form a heterotrimeric complex (Wieringa et al. 2003a). In infected cells, covalently linked GP_{2b}/GP_4 heterodimers associate with GP_3 to produce a $GP_{2b}/GP_3/GP_4$ complex that is required for incorporation of the three glycoproteins into virions. Following virus release, GP_3 becomes disulfide-linked to the GP_{2b}/GP_4 heterodimers, a postassembly maturation event that yields a complex of three covalently bound glycoproteins. Consequently, EAV particles contain both GP_{2b}/GP_4 heterodimers and $GP_{2b}/GP_3/GP_4$ heterotrimers (Wieringa et al. 2003a).

The above data indicate that EAV N, M, and GP_5 are the only structural proteins required for virus assembly, but that the disulfide-linked $GP_{2b}/GP_3/GP_4$ heterotrimer is required for virus infectivity, most likely because this complex is essential for attachment to the host cell surface. The higher order structure of the arterivirus E protein is unknown, but also this protein is essential for infectivity (Molenkamp et al. 2000) and may, in fact, be associated with the $GP_{2b}/GP_3/GP_4$ trimer (Wieringa et al. 2003b).

Immune responses

HUMORAL IMMUNITY

The surface glycoprotein, S (coronaviruses and toroviruses), and the major glycoprotein, GP_5 (arteriviruses), are the major inducers of neutralizing antibody during natural infection (Balasuriya et al. 2004a; Chirnside et al. 1995; Ostrowski et al. 2002; Spaan et al. 1988; Wissink et al. 2003). In the specific case of SARS-CoV, it also appears that the S protein is the only significant protective antigen among the structural proteins (Buchholz et al. 2004). The antigenic structure of the coronavirus S protein has been studied and the picture that emerges is complex (Cavanagh 1995). Essentially, the majority of virus neutralization (VN) epitopes seem to be located on the S1 subunit (or the amino terminal half of the S protein if it is not cleaved) and they are 'conformational' in the sense that they are comprised of amino acids that are brought into close proximity by the folding of the protein (Zhou et al. 2004). The VN epitopes are clustered into domains, one of which is usually immunodominant, although 2–3 domains may carry VN epitopes. Glycosylation seems to be an important component of VN epitope structure. Some studies have indicated that VN epitopes may be located on the S2 subunit (or carboxyl half of the protein) and that amino acids in the S2 subunit can modulate the recognition of VN epitopes located in the S1 subunit (Zhang et al. 2004a). It should be kept in mind that, although many VN epitopes have been defined, the mechanisms of virus neutralization remain essentially unknown.

Although the S and GP_5 proteins are the prime inducers of humoral immunity, antibody responses to other structural proteins may also have a role in protection. Some monoclonal antibodies specific for the MHV or TGEV M protein can neutralize virus infectivity in vitro (Fleming et al. 1989; Risco et al. 1995) and, as already mentioned, HE-specific antibodies are able to neutralize BCoV infectivity. It has been shown that E-specific antibodies are able to neutralize MHV infectivity in the presence of complement (Yu et al. 1994). The relevance of these observations to the situation in vivo is, however, unclear. The arterivirus, PRRSV, can be neutralized by monoclonal antibodies recognizing the ectodomain of the GP_4 protein (Meulenberg et al. 1997; van Nieuwstadt et al. 1996) and recombinant EAV N protein is able to induce neutralizing antibodies in mice (Tobiasch et al. 2001). Finally, immunization studies using alphavirus-based expression vectors have shown that the co-expression of EAV GP_5 and M is required for the induction of neutralizing antibodies in mice and horses (Balasuriya et al. 2000, 2002), although other reports indicate that the GP_5 ectodomain alone may suffice (Castillo-Olivares et al. 2001). A recombinant EAV lacking the immunodominant region of the GP_5 ectodomain was found to be viable and able to induce protective immunity in horses, indicating that immune effector mechanisms other than neutralizing antibodies binding to this region of GP_5 play an important role in protection against infection (Castillo-Olivares et al. 2003b).

CELL-MEDIATED IMMUNITY

As for most other viruses, the cell-mediated immune response to coronavirus and arterivirus infection is less well characterized than the humoral immune response. There is good evidence that the cell-mediated response is important in a variety of natural infections (Castillo-Olivares et al. 2003a; Loa et al. 2001; Paltrinieri et al. 1998) but, for technical reasons, most of the information we have relates to murine infections (MHV or LDV), often in an experimental setting. The coronavirus S, M, and N proteins, as well as the arterivirus N protein, are targets for cellular immune recognition (Plagemann 1996; Yang et al. 2004b). In a few cases, specific T-cell epitopes have been defined and helper or cytotoxic functions have been attributed to T-cell subpopulations. There is some preliminary evidence that nonstructural proteins may also represent T-cell immunogens (Stohlman et al. 1993).

In addition to MHC-restricted immune responses, coronavirus infections elicit lymphokine responses. Recent studies indicate that SARS-CoV infection elicits a response that is characterized by elevated levels of IL-6 cytokine, MCP-1, and IP-10 chemokines (Jones et al. 2004; Zhang et al. 2004b). Also, it is interesting to

note that the SARS-CoV nucleocapsid protein has been shown to regulate cellular signaling (Subbarao et al. 2004). MHV infection of 129/Sv mice triggers a transient increase in the level of IL-12 (p40) mRNA present in pooled spleen cells (Coutelier et al. 1995). Also, the M protein of TGEV can induce, directly or indirectly, the production of interferon-α in lymphocytes (Baudoux et al. 1998, de Haan et al. 2003). The significance of these types of response for innate immunity has not yet been defined but there seems little doubt that they play an important role in particular situations.

CLINICAL AND PATHOLOGICAL ASPECTS

Introduction

The spectrum of disease caused by coronaviruses and arteriviruses is summarized in Table 3. As is the case with many viruses, the majority of infections are asymptomatic, perhaps reflecting the pathogenic equilibrium reached during the co-evolution of host and pathogen. Many of the clinical diseases listed in Table 3 are, in fact, manifested only in immunodeficient animals (e.g. neonates or during pregnancy). In contrast, when a nonnatural host is infected, or when the natural host is infected by an unusual route or virus variant, fulminant disease can also ensue. In the following review, only natural infections of major importance are discussed. For a discussion of less common and experimental infections with coronaviruses and arteriviruses the reader is referred to other review articles (Dales and Anderson 1995; Foley and Leutenegger 2001; Garwes 1995; Haring and Perlman 2001; Holmes 2001b; Koopmans and Horzinek 1995; Paul et al. 2003; Plagemann et al. 1995).

Coronaviruses

HUMAN CORONAVIRUSES (INCLUDING SARS-COV)

Human coronaviruses (HCoV) are accepted as a major cause of respiratory tract illness in humans. HCoVs are

MPS, mononuclear phagocyte system. ++, main target for infection; +, secondary target for infection. ?, circumstantial evidence of infection or disease. Other targets of infection are: [a]kidney; [b]serous membranes; [c]liver; [d]salivary, lacrimal glands; [e]arteries.

grouped into three major groups that are prototyped by HCoV-229E, HCoV-OC43, and SARS-CoV. HCoV-229E and HCoV-OC43 are mainly associated with common colds (Myint 1995). It has been estimated that up to 30 percent of clinical cases are due to infections with these two viruses. Typically, after an incubation period of about 3 days, patients develop general malaise, headache, nasal discharge, sneezing, and a mild sore throat (Tyrrell et al. 1993). About one-tenth of patients also have a fever and one-fifth will have a cough. Although most of these infections remain restricted to the upper respiratory tract there is evidence that HCoV-229E and HCoV-OC43 may also cause severe lower respiratory tract illness (El-Sahly et al. 2000; Falsey et al. 2002; Pene et al. 2003; Vabret et al. 2003; van Elden et al. 2004). Also, HCoV-NL63, a recently isolated HCoV that is closely related to HCoV-229E, was reported to be associated with lower respiratory tract infections, such as pneumonia and bronchiolitis, in young children (Fouchier et al. 2004, van der Hoek et al. 2004; Esper et al. 2005). Very recently, yet another human coronavirus, HCoV-HKU1, has been isolated from patients with pneumonia (Woo et al. 2005). HCoV-229E and HCoV-OC43 have also been associated with diseases outside the respiratory tract, for example with gastroenteritis (Zhang et al. 1994) and, possibly, neurological diseases (Arbour et al. 2000; Stewart et al. 1992). HCoV infections are thought to be transmitted by aerosols. The peak incidence of infection is in the winter and spring (Lina et al. 1996). Somewhere between 10 percent and 20 percent of individuals have serological responses indicative of HCoV-229E or HCoV-OC43 infection in any one year, although this figure may increase to 35 percent in some years (Monto and Lim 1974). A high percentage of infections occur despite pre-existing antibody, and the frequency of infection gradually diminishes with age (Callow et al. 1990). Little is known about the pathogenesis and immune response to HCoV-229E and HCoV-OC43 infection, mainly because there is no animal model available. Replication of the virus is optimal at 33–34°C and takes place in ciliated cells of the nasal epithelium (Afzelius 1994). Serum antibodies rise about 1 week after infection, peak at 2 weeks, and decline to low levels after about 12–18 months. The serum antibody response is mainly directed toward the surface protein although membrane- and nucleoprotein-specific immunoglobulins are also synthesized.

With very few exceptions, HCoVs are difficult to isolate and, even after adaptation to tissue culture, propagation in vitro is inefficient. Thus, the isolation of HCoVs in organ or tissue culture and the identification of HCoVs by electron microscopy or immunoelectron microscopy is possible only in specialized laboratories. Until a few years ago, the diagnosis of HCoV-229E and HCoV-OC43 infection relied mainly on serological methods, including, for example, enzyme-linked immunosorbent assay (ELISA), neutralization, immunofluorescence, western-blotting, and complement fixation (Myint 1995). More recently, the detection of viral antigens and, in particular, RT-PCR methods have become the standard approach to the rapid diagnosis of 229E and OC43 infections (Hays and Myint 1998; Sizun et al. 1998; Stephensen et al. 1999; Vabret et al. 2001; Vallet et al. 2004; van Elden et al. 2004). Despite these advances, the detection of HCoV-229E and HCoV-OC43 infections is not generally done in routine diagnostic laboratories.

Another disease caused by a human coronavirus is the severe acute respiratory syndrome (SARS), a life-threatening and rapidly progressing form of pneumonia that first emerged in Guangdong province, China, in November 2002. Between February and July 2003 the virus infected more than 8 400 people worldwide and at the end of the epidemic more than 800 deaths had been recorded. SARS was shown to be caused by a previously unknown coronavirus, which was named SARS-CoV (Drosten et al. 2003; Ksiazek et al. 2003; Kuiken et al. 2003; Peiris et al. 2003a). The virus is generally believed to have evolved from an animal coronavirus that only recently crossed the species barrier to humans, although the natural reservoir of SARS-CoV remains to be identified (Guan et al. 2003). There is limited evidence that a very low number of people already had antibodies to SARS-CoV before the SARS outbreak, suggesting previous exposure to the same or a related coronavirus (Zheng et al. 2004). SARS-CoV is only distantly related to other animal and human coronaviruses (Marra et al. 2003; Rota et al. 2003) and has been classified (as the prototype of a new subgroup) in the coronavirus group 2, which also includes HCoV-OC43 (Gorbalenya et al. 2004; Snijder et al. 2003a). SARS-CoV is spread mainly by the respiratory and, possibly, fecal–oral routes (Ho et al. 2003b; Poutanen and McGeer 2004; Seto et al. 2003). Transmission requires close contact and, therefore, often occurs in hospital and health care settings from patients who are severely ill. It is generally believed that the virus is not transmitted from asymptomatic cases to contacts (Lee et al. 2003b). The clinical course of SARS is characterized by early nonspecific influenza-like symptoms, including persistent fever, chills, rigors, myalgia, and general malaise. After several days, respiratory symptoms (dry cough, rhinorrhea, shortness of breath) and gastrointestinal symptoms (nausea, vomiting, diarrhea) develop in most cases (Lee et al. 2003c; Loutfy et al. 2003; Ooi and Daqing 2003; Peiris et al. 2003a,b; Rainer 2004). About 8 days after the onset of fever, there is a rapid, often bilateral progression of ground glass opacies on chest radiographs. In a significant proportion of patients, multifocal and diffuse consolidation develops. The lung pathology may be associated with further complications, such as pneumomediastinum and pneumothorax, resulting in dramatically decreasing arterial oxygen saturation (Ooi and Daqing 2003; Peiris et al. 2003b). About 20 percent

of the patients deteriorate with evidence of an acute respiratory distress syndrome (ARDS), requiring admission to an intensive care unit and mechanical ventilation. The overall case-fatality rate determined at the end of the outbreak in July 2003 was calculated to be about 11 percent. The fatality rate was extremely low in children (close to 0 percent), whereas in patients older than 65 years the mortality approached 50 percent. The laboratory diagnosis of SARS is based on RT-PCR and serology. RT-PCR is done from nasopharyngeal aspirate and swab samples and, if available, specimens from the lower respiratory tract (Emery et al. 2004). Viral RNA is also detectable in feces, serum, plasma, and urine. Viral load in respiratory samples and fecal samples peak at around 10–12 days and 15–17 days, respectively, after illness onset (Chan et al. 2004). To detect SARS-CoV infection as early as possible (i.e. in the first week of illness), multiple clinical samples should be collected and analyzed simultaneously. Positive RT-PCR results must be confirmed using primers specific for different parts of the SARS-CoV genome and tests should be done with multiple clinical samples. Seroconversion is a relatively delayed phenomenon and, consequently, not suitable as a rapid diagnostic test. Generally, SARS-CoV-specific IgG becomes detectable after 10–15 days of illness or even later. Serological assays, therefore, remain the gold standard for retrospective studies but are less suitable for rapid diagnosis. Anti-SARS-CoV IgG in the serum can be detected by immunofluorescence, enzyme-linked immunosorbent assays, and neutralization tests, which correlate very well with each other. The first serological assays to be developed and used during the SARS epidemic in 2003 were based on virus antigen produced from SARS-CoV-infected cells. This rapid development was possible because SARS-CoV, in contrast to most other HCoVs, grows to high titers in cell culture (for example, in Vero cells). Meanwhile, numerous diagnostic assays based on recombinant nucleocapsid (N), spike (S), and membrane (M) protein antigens are available, providing convenient tools that do not require biosafety level 3 laboratories. SARS-CoV antibodies show only very little cross-reactivity with antibodies specific for other human coronaviruses (Ksiazek et al. 2003). Negative SARS-CoV serology at 28 days after onset of symptoms is generally accepted to exclude the diagnosis of SARS-CoV infection.

To date, there have been no high-quality studies of any antiviral or immunosuppressive therapy. The few available studies indicate that therapies based on antiviral agents, such as ribavirin and oseltamivir, and immunosuppressive steroid therapy, may have severe side effects but there is only anecdotal evidence that these drugs significantly reduce the severity of the disease (Cyranoski 2003; Ho et al. 2003a; Loutfy et al. 2003; So et al. 2003; Tsang et al. 2003). However, SARS-CoV and other human coronaviruses proved to be sensitive to treatment with type I interferons, both in cell culture and animal models (Cinatl et al. 2003; Haagmans et al. 2004; Hensley et al. 2004; Hertzig et al. 2004), suggesting that type I interferons are promising drugs for SARS treatment protocols, which is consistent with pilot (mainly uncontrolled) clinical studies (Cinatl et al. 2004).

Thus far, the pathogenesis of SARS has been only poorly understood. The fact that, despite significantly reduced virus load, some patients deteriorate in the second week of illness suggests that the lung damage may be due to immunopathological mechanisms rather than virus replication. Animal models suitable to address this possibility and to investigate SARS-CoV pathogenesis in general are becoming increasingly available (Fouchier et al. 2003; Martina et al. 2003; Subbarao et al. 2004, ter Meulen et al. 2004; Wentworth et al. 2004; Yang et al. 2004b). The SARS outbreak has inspired many studies into virtually every aspect of SARS-CoV biology. The studies revealed promising therapeutic approaches, some of which might be used to develop drugs that are suitable to treat SARS-CoV infections. Candidate antivirals include fusion inhibitors (Bosch et al. 2004; Liu et al. 2004), inhibitors of the SARS-CoV main proteinase (Anand et al. 2003; Bacha et al. 2004; Hsu et al. 2004), recombinant antibodies (ter Meulen et al. 2004), and small compounds identified by screening of drug libraries (Wu et al. 2004). Finally, promising candidate vaccines have been developed that proved to be protective in SARS animal models (Bisht et al. 2004; Buchholz et al. 2004; Bukreyev et al. 2004; Yang et al. 2004b). The rapid progress in the improvement of diagnostic tests and the development of vaccines and antivirals should help to control future outbreaks of SARS more effectively.

AVIAN INFECTIOUS BRONCHITIS VIRUS

IBV is a pathogen of economic importance to the poultry industry worldwide. It causes a highly contagious disease affecting the respiratory, reproductive, neurological, and renal systems of chickens. IBV infection results in a drop in egg production in adult birds and damages the developing reproductive system in young birds. Infection of the respiratory tract, most probably by aerosols, is the most important route of transmission. Young chickens are most susceptible to infection and the clinical signs include nasal discharge, sneezing, coughing, and tracheal rales. IBV infection predisposes chickens to infection with secondary pathogens. Even young chickens will usually recover from an uncomplicated IBV infection, but the incidence of IBV-related nephritis, which can result in high mortality rates, seems to be increasing (Cavanagh and Naqi 2003; Cook and Mockett 1995; Ignjatovic and Sapats 2000; Lee et al. 2004).

Chickens respond to IBV infection by producing specific humoral antibodies of the IgM, IgG, and IgA

subclasses. The major viral antigens are the S and M proteins, and the S protein is a major immunogen. High concentrations of VN antibodies are thought to prevent the spread of virus from its primary replication site to the reproductive and renal organs. Local immune responses, in particular IgA, play a significant role in controlling the respiratory infection. Finally, cell-mediated immune responses also develop after IBV infection. Cell-mediated immune responses to the S, N, and M proteins have been demonstrated (Ignjatovic and Galli 1993). At the moment, however, the relationship between cell-mediated immune responses and the degree of protective or long-term immunity has not been defined.

The diagnosis of IBV infection, in common with most other viruses, depends on three approaches: (1) isolation of the virus; (2) demonstration of a specific antibody response, usually by serological methods; and (3) demonstration of viral nucleic acid in clinical material.

IBV can be isolated in tracheal organ cultures and embryonated eggs and propagated in tissue cultures. Infected allantoic fluid and tracheal organ culture supernatant often contain enough virus particles to be visualized directly by electron microscopy. Alternatively, IBV isolates can be identified by immunofluorescence using polyclonal antisera or by antigen assays based on monoclonal antibodies. The existence of strain-specific monoclonal antibodies has also led to the development of serotype-specific ELISAs (Karaca and Naqi 1993).

A range of serological tests are available to detect IBV antibodies. They include immunofluorescence, hemagglutinin inhibition, ELISA, and virus neutralization. Probably the most sensitive tests are ELISAs using purified virus as antigen. In the future, it can be expected that these types of test will be significantly improved by the use of recombinant antigens (Chen et al. 2003; Guy et al. 2002; Wang et al. 2002). It is possible to detect IBV nucleic acids directly in clinical material. PCR is a rapid and sensitive method to amplify and identify IBV RNA (Jackwood et al. 2003; Liu et al. 2003). Combined with nucleotide sequencing (Lee et al. 2003a), PCR will probably also be the preferred method for distinguishing between IBV serotypes.

At the present time, the control of IBV relies almost exclusively on vaccination and management. Both live attenuated and inactivated vaccines are available. It is generally believed that both vaccines can be used, usually in combination, to induce high levels of humoral antibody and that immunity represents protection against reproductive and renal disease rather than protection against respiratory infection (Cook and Mockett 1995). There are also two major problems associated with the use of vaccine. First, there are many serotypes of IBV and, although it is not necessary to develop a different vaccine for each serotype, occasionally serotypes emerge against which existing vaccines are not fully effective. Secondly, although some serotypes probably emerge by antigenic drift, there is at least circumstantial evidence to suggest that they may also emerge by recombination, possibly involving the live vaccine virus itself (Cavanagh 2003; Lee and Jackwood 2000).

PORCINE TRANSMISSIBLE GASTROENTERITIS VIRUS

The severity of disease caused by porcine transmissible gastroenteritis virus TGEV is related to the age of the animal. Infection of the piglet during the first 2 weeks of life causes vomiting followed by profuse, watery diarrhea that eventually results in dehydration and frequently death within 2–5 days. In older pigs, similar clinical signs are manifested but the mortality rate drops as the body weight of the animal at the time of infection increases. Transmission of TGEV is primarily from the ingestion of contaminated material, usually feces or milk, and possibly via aerosols (Enjuanes and Van der Zeijst 1995; Garwes 1995). TGEV has been reported in a large number of countries, but with different incidence and prevalence of disease. In countries where pig breeding has not been intensified, transmissible gastroenteritis is essentially epizootic with an incidence of disease every 2–3 years. In this situation, new outbreaks of disease are probably due to the cyclic reintroduction of virus. In countries with intensive pig breeding, transmissible gastroenteritis infection has become essentially enzootic. In this situation, the virus probably establishes a persistent infection in adult animals, in the gut or respiratory tract.

The pathogenesis and immune response to TGEV infection, especially in newborn animals, are quite well understood. The virus primarily infects and replicates in the apical tubovascular system of villous absorptive cells in the jejunum and ileum. Clinical signs seem to result from an increase in osmotic pressure in the lumen of the small intestine, caused by a failure to absorb milk lactose combined with an abnormal level of sodium secretion into the lumen (Garwes 1995). Because immunity requires the secretion of antibodies into the lumen of the gut, the rapid progression of the disease in the newborn animal probably provides insufficient time for immunity to develop, irrespective of whether the animals have reached a state of immune competence. The main source of immune protection for neonates, therefore, has to be antibodies provided by the mother in colostrum and milk (de Diego et al. 1992). Surprisingly, it has been shown that colostrum from nonimmune sows can also provide some degree of protection (Enjuanes & Van der Zeijst 1995).

Several techniques are available for the rapid diagnosis of TGEV infection, including immunofluorescence, ELISA, nucleic acid hybridization, and RT-PCR (Enjuanes and Van der Zeijst 1995; Kim et al. 2000, 2001, Liu et al. 2001a; Paton and Lowings 1997). Most importantly, a panel of type-, group-, and interspecies-

specific monoclonal antibodies have been developed to distinguish between viruses of the TGEV cluster, including PRCV (Sanchez et al. 1990). As described above, immune protection of piglets can be best achieved by natural lactogenic immunity provided by sows, by artificial lactogenic immunity using serum or protective monoclonal antibodies or, perhaps, by transgenic lactogenic immunity (Castilla et al. 1998). Virulent TGEV strains can be used to produce a solid immunity for both pregnant sows and their offspring (de Diego et al. 1992) but there is an obvious danger associated with this approach. Attenuated strains of TGEV and the PRCV variant have also been tested as vaccines but they have only limited efficacy (Saif and Wesley 1992). Efforts are being made to develop more effective vaccines. These may include noninfectious antigens that are targeted to the gut, and the use of live vectors with enteric tropism (Chen and Schifferli 2003, Lamphear et al. 2004; Liu et al. 2001b; Saif 1999; Sola et al. 2003).

FELINE CORONAVIRUS

Feline coronaviruses are a common cause of enteric disease in cats and, occasionally, they cause an immune-mediated disease known as feline infectious peritonitis (FIP). The enteric disease results in mild, transient diarrhoea that is self-limiting. FIP, however, is invariably lethal. Two distinct forms of FIP exist: the wet form, which is characterised by abdominal, and occasionally, pleural effusions, and the dry form, which is characterized by granuloma formation on the surface of tissues. In the dry form, the CNS is commonly involved but any organ may be affected. Feline coronavirus infection is enzootic in virtually all environments where large numbers of cats are kept and transmission is predominantly by the feco-oral route (de Groot and Horzinek 1995).

The patho-etiology of FIP is not well understood. It is known that purebred cats are predisposed to the development of FIP and the majority of cats develop FIP before 2 years of age (Foley et al. 1997; Poland et al. 1996). A widely held view is that FIP occurs when a cat is exposed to feline coronavirus variants that have mutated in the host and gained the ability to replicate in macrophages (Vennema et al. 1998). There is, however, no conclusive evidence to support this hypothesis. Also, it has been noted that, at least in experimental infections, seropositive cats develop an accelerated fulminating course of disease and this has been interpreted as evidence of 'antibody-dependent enhancement.' However, similar effects are seldom seen in natural infections (Hohdatsu et al. 1998). Finally, it has been postulated that a deregulated cytokine/chemokine response and the lack of an effective cell-mediated immune response plays a central role in the development of FIP (Paltrinieri et al. 2003). However, the available data is still preliminary.

With the exception of some laboratory-adapted strains, feline coronaviruses cannot be easily propagated in cell culture. Therefore infections are diagnosed by serological methods or, if the animals are shedding virus in the faeces, by using RT-PCR (Addie and Jarrett 2001; Addie et al. 2004; Addie et al. 2003). However, there is no specific diagnostic test for animals that are at increased risk of developing FIP or are in the earliest stages of the disease. Indeed, definitive diagnosis of FIP can only be made by histopathological examination of biopsy material or post-mortem material. As there is no effective treatment for FIP, environmental controls are currently the most powerful and widely used tools for the control of feline coronavirus infection. These include good hygiene, isolation, and early weaning. In the longer term, there is a clear need for an effective vaccine and/or the development of antiviral drugs that could be used to protect animals at greatest risk.

Toroviruses

BOVINE TOROVIRUS (PREVIOUSLY BREDA VIRUS)

There is clear evidence that torovirus infections are quite common in vertebrate species. Despite their potential veterinary and clinical relevance, the virus group has not been studied in great detail, in particular since propagation of toroviruses in cell culture has proven to be very difficult. Serological evidence of torovirus infection has been obtained in all ungulates that were tested using a bovine torovirus (BToV) neutralization assay (horses, cattle, sheep, goats, and pigs) and in rats, rabbits, and some species of feral mice (Weiss et al. 1984). Torovirus-like particles have also been observed and, in some cases, isolated from stool specimens from horses, cattle, pigs, humans, cats, and dogs (Koopmans and Horzinek 1995; Kroneman et al. 1998). Four torovirus genotypes were recently distinguished, exemplified by BToV (also known as bovine enteric torovirus), porcine torovirus (PToV), EToV, and human torovirus (HToV). In addition, sequence analysis revealed ample evidence for recurring intertypic recombination and predicts the existence of at least two additional, hitherto unknown, torovirus genotypes (Smits et al. 2003). It has been speculated that toroviruses may be associated with enteric disease in many species but, as yet, the only disease that can be definitely ascribed to a torovirus is BToV-related gastroenteritis in cattle.

Seroepidemiological studies in a number of countries show that the infection of cattle with BToV seems to be common throughout the world. In dairy cattle herds in the Netherlands, 85–95 percent of animals have antibodies to BToV by 1 year of age (Koopmans et al. 1989). Transmission probably takes place via the oral or the respiratory routes. BToV infections are usually limited to the gut, although there is some evidence for a

possible respiratory involvement. The clinical signs of infection are watery diarrhea with dehydration, weakness, and depression. Predominantly affected are young animals 2–3 weeks of age; by the time they are 3–4 months old, they have only very mild or no diarrhea, in association with virus shedding. There is some preliminary evidence that persistent BToV infection can be established in a herd (Koopmans et al. 1990).

The pathogenesis of BToV infection centers on the destruction of crypt and villus epithelial cells, particularly in the small intestine. Although the epithelial cells are rapidly replaced, the new cells lack a mature brush border and thus present insufficient absorptive surface and digestive enzymes. This decrease in absorptive and digestive capacity causes an accumulation of lactose in the gut lumen, which in turn results in water and electrolytic retention leading to diarrhea. At least in young animals, the immune response following infection is probably of secondary importance, because protection depends mainly on maternal antibodies derived from colostrum and milk.

Attempts to isolate and propagate toroviruses have proved unsuccessful. In cell or tissue culture, BToV as well as HToV and PToV, have not been replicated to date. The isolation of EToV was a unique event that could be repeated only with the field sample of a single horse. The diagnosis of BToV infection has thus relied on immunological methods for the detection of BToV antigen or BToV-specific antibodies. However, there is evidence that BToV-infected animals shed ELISA-detectable amounts of virus for only 2–3 days (Woode et al. 1982), and the purification of BToV antigens from the feces of experimentally infected gnotobiotic calves is a laborious and expensive procedure. Nucleic acid hybridization, RT-PCR, and ELISA methods have been developed for the detection of BToV in clinical material (Hoet et al. 2003; Koopmans et al. 1991, 1993) and are used for diagnostic purposes and epidemiological studies. The control of torovirus-related disease currently depends on good management practices.

Arteriviruses

EQUINE ARTERITIS VIRUS

EAV was first isolated in 1953 from an aborted equine fetus. Serological evidence suggests that EAV is widespread in the horse population (Timoney and McCollum 1988) but infections are generally subclinical and usually lead only to a mild, often unrecognized, infection of the respiratory tract. If the virus does cause overt disease, the clinical symptoms are acute anorexia and fever, usually accompanied by palpebral edema, conjunctivitis, nasal catarrh, and edema of the legs, genitals, and abdomen (Plagemann and Moennig 1992). The clinical symptoms of EAV infection vary widely, probably reflecting, at least in part, differences in virulence among EAV variants. Almost all naturally infected horses recover from EAV infection. Donkeys are the only other known host for the virus (Paweska 1994).

The primary mode of EAV transmission is assumed to be via the respiratory route by contact with aerosol secretions from acutely infected animals. The name 'equine arteritis virus' was derived from the characteristic necrosis of small muscular arteries following infection. Of greatest concern to the horse breeding industry, however, is the fact that the virus frequently causes abortion in pregnant mares (Golnik et al. 1986). Furthermore, a carrier state exists in seropositive stallions in which EAV is produced in the semen (Balasuriya et al. 2004b). These 'shedding stallions' may thus infect brood mares by the venereal route.

Studies of experimentally infected horses have indicated that, as with other arteriviruses, the initial replication of EAV takes place in lung macrophages. The virus infects the bronchial lymph nodes and then spreads throughout the body via the circulatory system. The cause of abortion in pregnant mares has not yet been elucidated. EAV-induced, macrophage-derived cytokines may contribute to the pathogenesis of EAV and the magnitude of the cytokine response may be linked to the virulence of the infecting virus strain (Moore et al. 2003). Neutralizing antibodies, mainly of the IgG class, are induced within a week of EAV infection, and this clears the virus from the circulation. Clearly, however, this does not always prevent the virus from establishing a persistent infection, particularly in stallions. Neutralizing antibodies generally persist for years, and protective immunity is presumed to be lifelong. Only one EAV serotype has been recognized, although European and North-American genotypes can be discriminated (Stadejek et al. 1999). As described above, the EAV GP_5 glycoprotein is the main inducer of neutralizing antibodies (Balasuriya et al. 2004a; Balasuriya et al. 2002; Castillo-Olivares et al. 2001; Chirnside et al. 1995).

Traditionally, the diagnosis of EAV infection has been based on the isolation and propagation of virus in tissue culture. The clinical materials most often used are nasopharyngeal, vaginal and rectal swabs or a buffy coat fraction from blood or semen. Rabbit kidney (RK-13), baby hamster kidney (BHK-21), and Vero cells are susceptible to infection and develop characteristic cytopathic effects.

Attempts to isolate virus from field cases have sometimes proved difficult. Several immunological assays for measuring EAV-specific antibodies in horse sera are available but the detection of neutralizing antibodies ($TCID_{50}$ and plaque reduction assays) are used most commonly. The determination of the nucleotide sequence of the EAV genome has also allowed the development of assays based on RT-PCR (Chirnside and Spaan 1990; Gilbert et al. 1997; St-Laurent et al. 1994). The control of EAV infection relies on a combination of vaccination and containment (Chirnside 1992;

Plagemann and Moennig 1992). At present, a live-attenuated and a killed virus vaccines are available. The live vaccine induces long-lasting protection against clinical disease but does not prevent reinfection with wild-type virus or temporary virus shedding (McCollum 1986). To avoid this problem, a formalin-inactivated vaccine (Fukunaga et al. 1984) has been developed. Increased knowledge of the antigenic properties of the EAV GP_5 protein may provide the basis for the development of an EAV subunit vaccine (Balasuriya et al. 2002; Castillo-Olivares et al. 2001; Chirnside et al. 1995; Giese et al. 2002). Furthermore, the development of reverse genetics systems for EAV (van Dinten et al. 1997) has opened the possibility of the development of vaccines based on the genetic engineering of the virus genome (Castillo-Olivares et al. 2003b; de Vries et al. 2001; Zevenhoven-Dobbe et al. 2004).

Porcine reproductive and respiratory syndrome virus

PRRSV is responsible for respiratory disease in pigs of all ages and for abortions and stillbirths in pregnant sows. The clinical signs of infection are transient fever, anorexia, and respiratory distress. Mortality is generally seen only in young piglets and is often associated with secondary infections (Meredith 1993; Plagemann 1996). Within the herd, PRRSV is thought to be transmitted mainly via aerosols but, as in the case of EAV, sexual transmission also occurs (Sur et al. 1997). The virus is present in nasal secretions and swine can be readily infected by intranasal inoculation. Fecal–oral transmission may, however, also take place and infection between herds may involve the movement of infected animals or fomites. In pregnant sows, PRRSV can be transmitted transplacentally, leading to reproductive failure in late gestation. The disease associated with PRRSV first appeared in the USA in the late 1980s. The first incidence of the disease in Europe was in northern Germany in 1991 and the virus is now common in the Netherlands and the UK. As with TGEV, the disease associated with PRRSV infection was originally epizootic, but more recently the incidence of acute disease has decreased and mild, even unapparent, infections are becoming more commonplace.

Lung macrophages are the primary site of PRRSV infection and replication. Their destruction is probably the cause of the increased susceptibility of infected pigs to secondary bacterial infections. The virus may also spread to other organs. In addition to interstitial pneumonia, lymphocytic encephalitis is a common lesion found in PRRSV-infected animals. The course of development of anti-PRRSV immunity is unconventional and many issues remain to be studied in detail (Murtaugh et al. 2002). The virus does not elicit the strong innate immune response seen in many other viral pathogens. Humoral and cell-mediated immunity is induced and clears the virus from the circulation but not from lymphoid tissues, where the infection becomes persistent. As with other arteriviruses, the initial phase of PRRSV infection is characterized by transient suppression of the cellular immune response coupled with an enhanced response to T-cell-dependent and T-cell-independent antigens (Murtaugh et al. 1993). The weak cell-mediated immune response suggests that PRRSV suppresses T-cell recognition of infected macrophages (Xiao et al. 2004). PRRSV-specific humoral antibodies can be detected 1–2 weeks after infection and peak after 5–6 weeks. The neutralizing antibody component reaches a maximum after 4–6 weeks and, thereafter, virus is generally cleared from the circulation. There is evidence that virus may persist in swine herds for periods of 2 years or longer but it is not clear whether this represents persistence in the individual animal, reinfection of animals, or the infection of animals that have escaped earlier encounters with the virus.

The diagnosis and control of PRRSV infections still represents a significant problem. In tissue culture, PRRSV is most successfully isolated and propagated in primary pig lung macrophages. However, the costs involved preclude this as a routine diagnostic procedure. A number of continuous cell lines can be used for virus propagation but they do not seem to be equally susceptible to all isolates. Serologically, PRRSV infections can be detected by virus neutralization, immunofluorescence, and immunoperoxidase staining. However, it is clear that many isolates of PRRSV differ antigenically and it will be some time before the extent of this variation has been fully characterized (Drew et al. 1995). Finally, the detection of PRRSV RNA using RT-PCR is under development (Legeay et al. 1997; Suarez et al. 1994; Van-Woensel et al. 1994) and promises to be the method of choice for the detection of low levels of viral RNA in the tissues of infected pigs. Control measures essentially consist of the eradication of infected herds and restrictions on the movement of pigs from enzootic areas. Live-attentuated and killed vaccines are available to protect pigs. However, adverse effects of vaccination of Danish pig herds with a modified live PRRS vaccine have been described (Botner 1997), which were probably caused by reversion of the vaccine virus to virulence. Acute PRRS-like symptoms, including an increasing number of abortions and stillborn piglets, were experienced in vaccinated herds. Furthermore, vaccine virus was transmitted from vaccinated to nonvaccinated boars in several cases, resulting in viremia and shedding of vaccine virus into semen (Madsen et al. 1998). In this respect, the killed vaccines are safer but are less efficacious in the induction of protection. Promising results were obtained in DNA vaccination experiments with plasmids expressing the GP_5 protein of PRRSV (Pirzadeh and Dea 1998). Neutralizing antibodies and lymphocyte proliferation

responses were detected in DNA-vaccinated pigs and the spread and clinical signs of challenge virus was reduced. As in the case of EAV, the immunogenic properties of the GP_5 ectodomain (Plagemann 2004; Wissink et al. 2003) suggest that the PRRSV major glycoprotein might be a good candidate for a DNA-based subunit vaccine. In addition, following the development of reverse genetics systems for PRRSV (Meulenberg et al. 1998; Nielsen et al. 2003; Truong et al. 2004), the first results from studies using vaccine viruses that have been attenuated by genetic engineering have recently been reported (Verheije et al. 2003).

Picornaviruses

PHILIP MINOR

Properties of the viruses	2	Control of enteroviral infections	22
Clinical and pathological aspects	13	Future prospects	27
Epidemiology	18	References	28
Laboratory diagnosis	20		

The picornaviruses cause a number of diseases of animals and humans of varying degrees of severity. The earliest record of a human disease believed to be caused by a virus is an Egyptian funerary stela of about 1 300 BC depicting a priest with the typical withered limb and dropped foot deformity of poli omyelitis, caused by *Poliovirus*, a picornavirus of the *Enterovirus* genus. In 1909, the virus was transmitted from the spinal cord of a fatal case to monkeys by Landsteiner and Popper. Enders et al. (1949) showed that poliovirus could be grown in primate cells of non-neural origin, and the isolation of other enteroviruses followed. Coxsackie virus was isolated from two children with paralytic disease from the town of Coxsackie in New York State in 1948 by the inoculation of newborn mice with fecal extracts (Dalldorf and Sickles 1948). Robbins and co-workers isolated echoviruses (enterocytopathic human orphan viruses) from healthy children in 1951. The echo-, polio- and coxsackie viruses, with more recently discovered viruses identified by number, are classified as enteroviruses, as shown in Table 1. The classification of the picornaviruses has been extensively reviewed and modified over the last few years and now relies mainly on molecular approaches.

The *Rhinovirus* genus of the picornavirus family is one of the causative agents of the common cold. Kruse (1914) first demonstrated that a cold could be transmitted by bacteria-free filtrates. The Common Cold Research Unit at Salisbury (UK) was established in 1946 and investigation of transmission of the common cold to human volunteers eventually led to the cultivation of the virus in vitro. In the USA, two cytopathogenic agents, JH and 2060, were described (Price et al. 1959) and were originally classified as echovirus 28, later being reclassified as *human rhinovirus A*, the type species of the genus (Kapikian et al. 1967). In 1960, Tyrrell and Parsons found that other viruses that caused common colds could be propagated in cultures of human embryonic kidney cells rolled at 33°C in medium with low pH (Tyrrell and Parsons 1960). This observation and the introduction of semicontinuous strains of diploid human embryonic lung fibroblasts (Hayflick and Moorhead 1961) led to a rapid increase in the number of

Table 1 Enterovirus *serotypes*

Group[a]	Major disease
Polioviruses 1–3	Paralytic poliomyelitis Aseptic meningitis
Coxsackie viruses A1–22, 24	Aseptic meningitis Herpangina Conjunctivitis (A24)
Coxsackie viruses B1–6	Aseptic meningitis Fatal neonatal disease Pleurodynia Myo- or pericarditis
Echoviruses 1–9, 11–21, 24–27, 29–34	Aseptic meningitis Rashes Febrile illness
Enteroviruses 68–71	Conjunctivitis (enterovirus 70) Polio-like illness (enterovirus 71)

Echovirus 9 = coxsackie virus A23; echovirus 10 = reovirus; echovirus 28 = rhinovirus; echovirus 34 = coxsackie virus A24.

a) In the current report of the International Committee on Taxonomy of Viruses these viruses are prefixed 'human' to distinguish them from animal viruses where relevant.

viruses isolated. Rhinoviruses were also isolated from horses (Plummer 1963) and cattle (Bögel and Böhm 1962).

The Rhinovirus Collaborative Programme of the World Health Organization authenticated 100 serotypes of rhinovirus over the next 20 years (Hamparian et al. 1987).

Foot-and-mouth disease virus (FMDV) was the first non-plant virus to be discovered (Loeffler and Frosch 1898).

PROPERTIES OF THE VIRUSES

The picornaviruses are small RNA-containing viruses. The complete sequences of the genomic RNA of many strains of picornaviruses have been determined, the first being that of the type 1 poliovirus strain Mahoney (Kitamura et al. 1981), and the atomic structures of representative viruses of each of the various genera have been resolved by X-ray crystallography (Hogle et al. 1985; Rossmann et al. 1985; Ming et al. 1987; Acharya et al. 1989). The discussion of the detailed molecular virology that follows refers to poliovirus except where stated otherwise.

Classification

The six genera that make up the *Picornaviridae* are:

- the enteroviruses (Table 1)
- the rhinoviruses
- the aphthoviruses, which cause foot-and-mouth disease of cattle
- the cardioviruses of mice, which include mengo virus and *Encephalomyocarditis virus* (EMCV) as well as Theiler's virus
- the hepatoviruses, which include hepatitis A viruses (described in Hepatitis A and E)
- the parechoviruses, which encompass the viruses previously designated echovirus 22 and echovirus 23.

Comparisons of the sequences of the virus genomes play an essential role in the classification scheme. In particular, Theiler's virus and *Hepatitis A virus* were moved from the enteroviruses mainly because of the nature of their genomic organization and sequence, although they also have particular pathogenic features, whereas echovirus 22 and echovirus 23 appear to be typical enteroviruses in all except their sequences, which are very different.

Molecular classification of the picornaviruses

Theiler's virus of mice is an acid-stable picornavirus which produces symptoms analogous to those of poliomyelitis in humans, and for many years it was classified as an *Enterovirus*. Determination of the sequence and later the structure of the virus showed that it was much more closely related to the cardioviruses of mice such as EMCV, and it was reassigned on this basis. Likewise, *Hepatitis A virus* was categorized as an *Enterovirus*, largely on the basis of its acid stability and its occurrence in the stool of infected individuals, but its pathogenesis is strikingly different from that of other enteroviruses and its sequence is uniquely placed among those of the other picornaviruses. It was also therefore reclassified.

Sequence comparisons made it clear that the rhinoviruses were very similar to the enteroviruses and a reevaluation of the whole basis of the classification took place, which has revealed the relationships between picornaviruses and enabled subclassifications to be made. The increasing use of molecular methods in clinical virology makes this a valuable and logical development.

Complete sequences of many picornaviruses are known and viruses can be classified into the appropriate genus on the basis of comparison of the amino acid sequences of any part of the coding region of the genome, including those encoding the structural proteins, P1, or the polymerase 3D (King et al. 2000). Dendrograms showing the relationships between the different picornavirus genera based on the P1 region are shown in Figure 1. Variation between genera is typically greater than 70 percent in terms of sequence, and the rhinoviruses and the enteroviruses are surprisingly closely related. If the nucleic acid sequence of the 5′ noncoding region is considered, however, only two clusters are evident.

Subclusters can be identified within a genus giving rise to the concept of the species. Members of a species are defined as sharing greater than 70 percent amino acid identity within P1, greater than 70 percent amino acid identity within the nonstructural proteins 2C and 3D combined, sharing a limited range of host cell receptors and natural host range, and having a degree of compatibility in certain aspects of virus multiplication. Species within the *Enterovirus* genus are shown in Figure 2. *Poliovirus* is currently classified in a different subspecies to the other group C species. There is reason to believe that the members of a species are able to exchange segments of their genomes by recombination more or less freely. Thus within the B species the P1 region is sufficient to identify a virus as a coxsackie virus B1 distinct from a coxsackie virus B3, for example, while comparisons of the nonstructural protein 3D are believed to be only able to identify a virus as a B species. Similarly within the C species it is not currently possible to distinguish a coxsackie virus A21 strain from a poliovirus by examination of the nonstructural proteins. This finding, if confirmed, implies that viruses within a species infect the same cell types and show a great deal of compatibility between their genomes, while

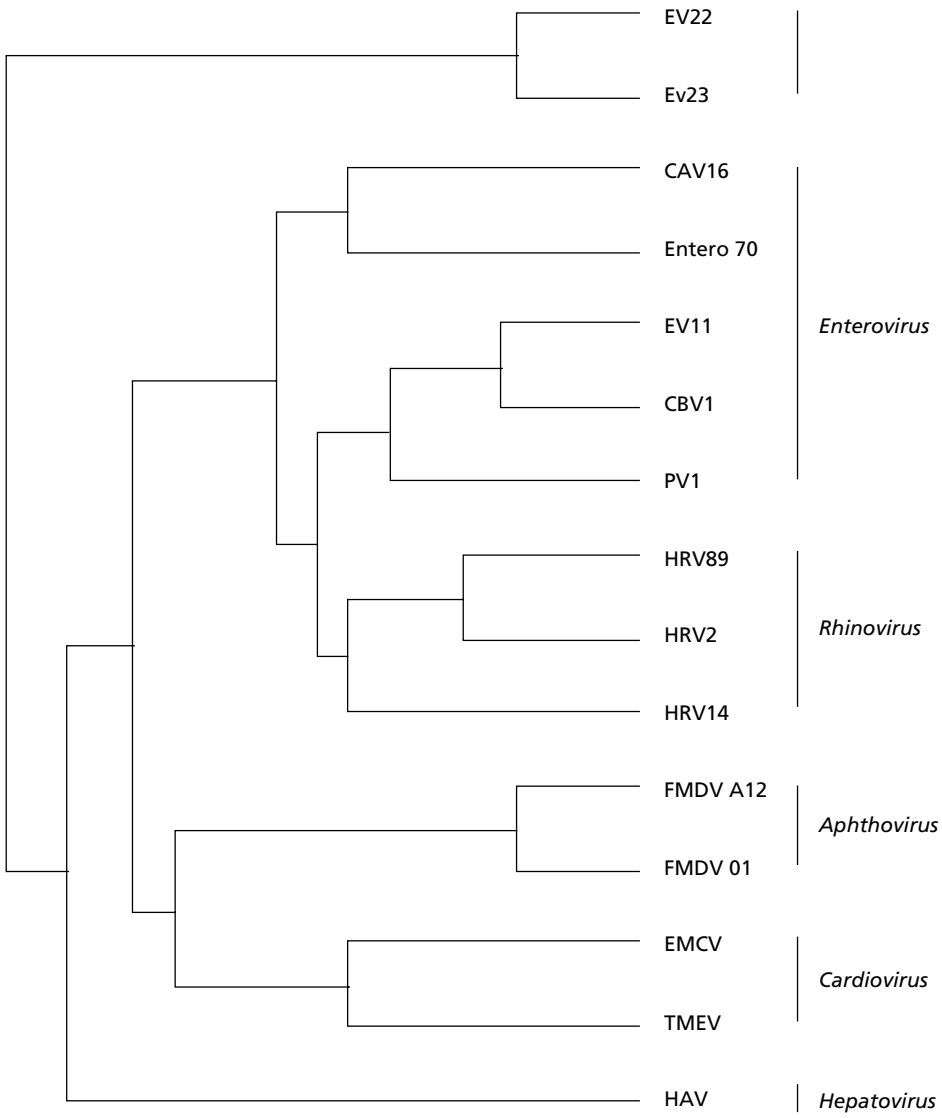

Figure 1 *Clustering of the picornavirus genera on the basis of comparison of the complete sequences of the genome. The viruses designated EV22 and EV23 (enterovirus 22 and enterovirus 23) are now classified as parechovirus 1 and parechovirus 2, respectively, on the basis of their highly distinct genomic sequences.*

those of different species are either unable to infect the same cell type naturally or have genomes which are incompatible with each other when segments are exchanged. Polioviruses which are recombinants between the vaccine strains and unknown species C enteroviruses have been isolated on several occasions, as discussed below (Kew et al. 2002).

Physical properties of picornaviruses of different genera

The viruses of the picornavirus genera share a number of characteristics (Palmenberg 1987), including size, icosahedral morphology, lack of a lipid envelope, a positive-sense RNA genome and the general arrangement of their structural proteins. The sedimentation coefficient is ca. 155–160S. The enteroviruses, cardioviruses, hepatoviruses, and parechsoviruses have a buoyant density in cesium chloride of 1.34 g/cm^3, the rhinoviruses of 1.40 g/cm^3, and the aphthoviruses of 1.43 g/cm^3. The enteroviruses and parechoviruses, unlike rhinoviruses or aphthoviruses, are totally stable at pH 4 and resistant at pH 2, and this property formed the basis of early classification schemes for the picornaviruses.

The genomes of both the aphtho- and the cardioviruses include a tract of cytidine residues not found in the other genera, and share a similar genomic structure distinct from that of the enteroviruses and rhinoviruses, as described below. The properties of the picornavirus genera are summarized in Table 2, p. 5.

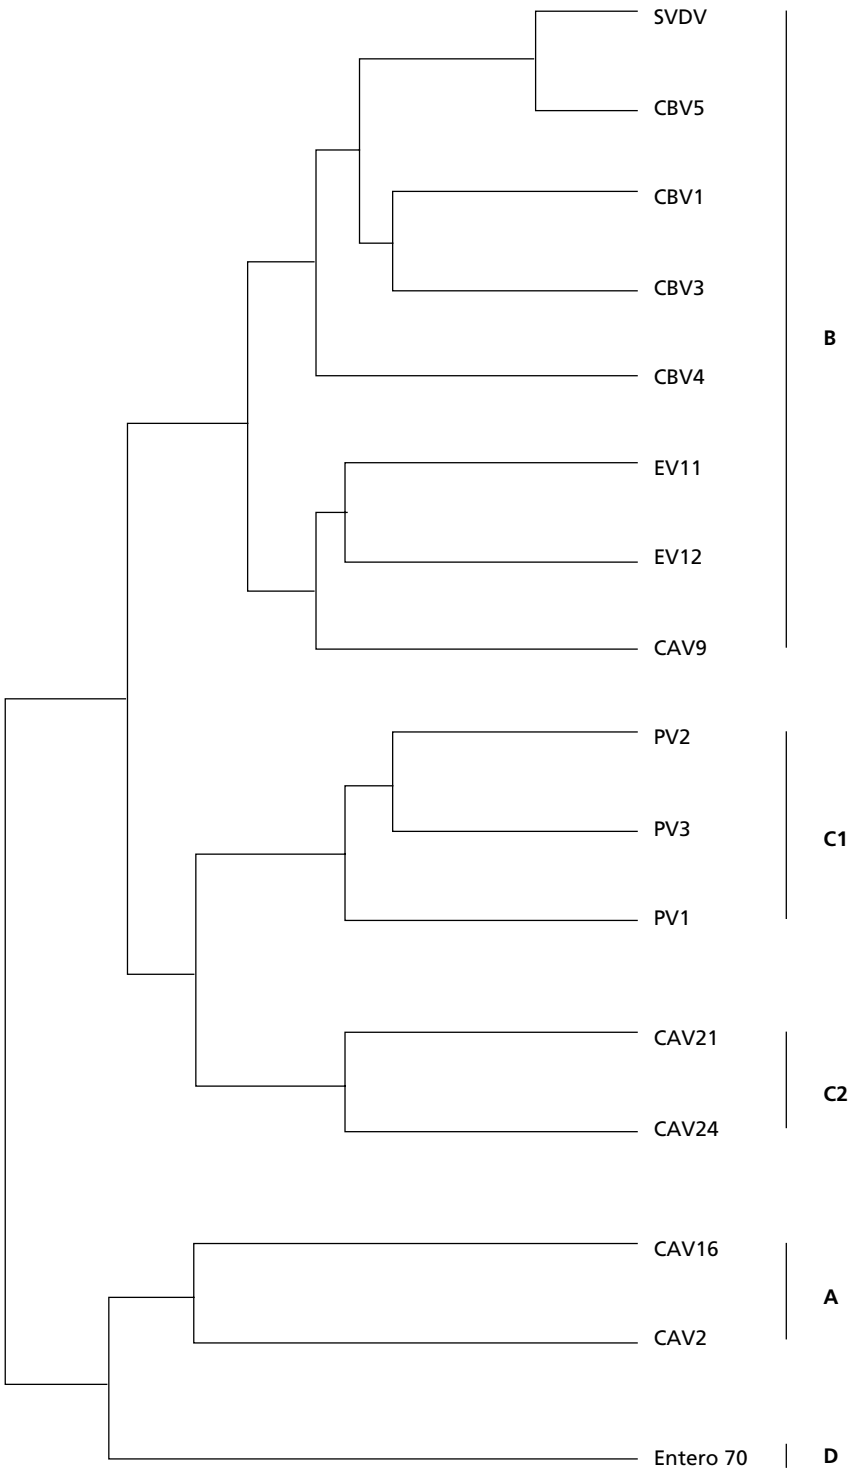

Figure 2 *Clustering of the human enteroviruses based on comparisons of the sequences of the structural proteins P1, showing the occurrence of species (clusters) A, B, C, and D.*

Biological and antigenic properties of subgroups

The enteroviruses are divided into various biological subgroups, which in general reflect the sequence classifications imperfectly. However, some are apparently related both serologically and by the sequence of the P1 region. For example, poliovirus 1 and poliovirus 2 share common antigens. Cross-relationships also exist between coxsackie viruses A3 and A8, A11 and A15, A13 and A18, echoviruses 1 and 8, 6 and 30, and 12 and 29.

a) Echoviruses 22 and 23.
b) It is not clear whether hepatoviruses contain VP4.

In general, the echoviruses may be biologically distinguished from the coxsackie viruses by their failure to cause pathological changes in newborn mice. However, most strains of echovirus 9 can produce flaccid paralysis in newborn mice, a finding that led to its early classification as coxsackie virus A23. Some strains of enterovirus 71 grow better in newborn mice than in cultures of primate cells. Conversely, coxsackie virus A9 is not pathogenic for mice unless passaged in cell culture, in which it grows readily, thus resembling the echoviruses.

The neutralization of rhinovirus infectivity by antisera is largely type specific, and is the basis of the numbering system by which rhinoviruses are classified into 100 serotypes (Hamparian et al. 1987). Minor serological variations may exist within a serotype. Within type 1 there are two subtypes, A and B: the low degree of cross-reaction between these subtypes may be reciprocal or one-way (Monto and Johnson 1966). 'Prime' strains of rhinovirus 22 that are antigenically broader than the prototype strain have been isolated (Schieble et al. 1970; Hamparian et al. 1987).

Resemblances to other viruses

A number of other viruses seem to be superficially similar to the picornaviruses. Astroviruses, which contain RNA and lack a lipid bilayer, are of similar size to picornaviruses, although with distinct morphology in electron micrographs. The caliciviruses are similar, but significantly larger, with a particle diameter of 30 nm, a characteristic morphology, and a capsid consisting of a single protein species. Other small round viruses are found in the intestinal tract and may be confused with the true enteroviruses; their relationship, if any, with the enteric picornaviruses is not clear (see Human enteric RNA viruses: Astroviruses).

However, the picornaviruses are similar in many ways, including particle structure and genomic organization to the spherical plant viruses such as cowpea mosaic virus and to insect viruses such as cricket paralysis virus. Similarly, the picornaviruses and togaviruses share some features of genomic strategy and organization. These relationships, which have been revealed by detailed molecular biological characterization of the viruses, suggest intriguing possibilities for the evolutionary origin of picornaviruses (see, for example, Rossmann 1987).

Morphology and structure

Picornaviruses usually appear in electron micrographs as roughly spherical particles not penetrated by negative

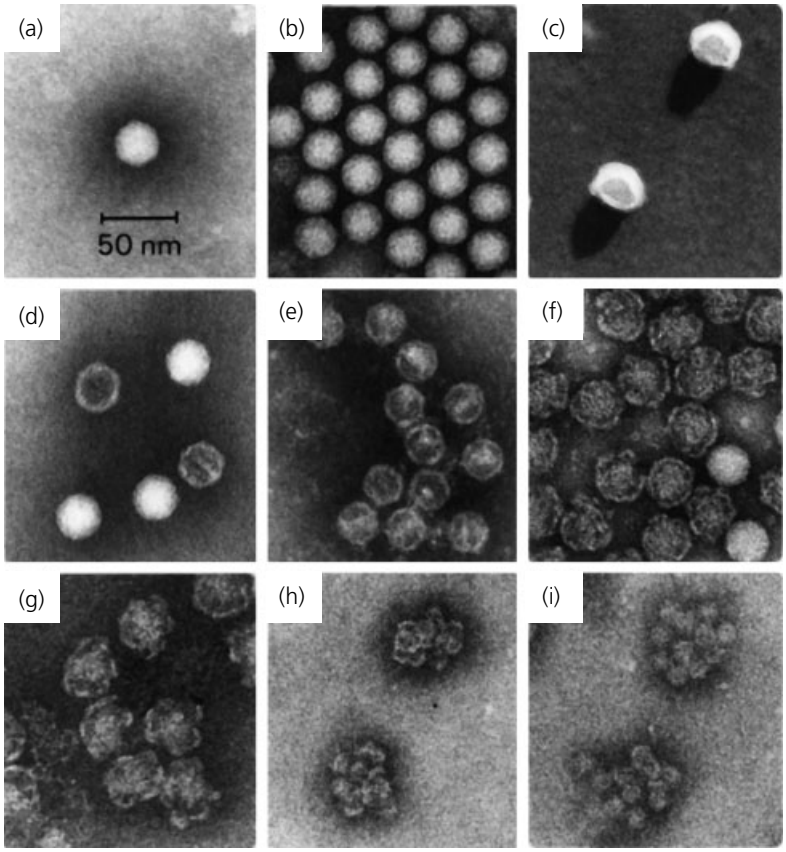

Figure 3 *Electron micrographs of poliovirus; all specimens (except c) stained with 4 percent sodium silicotungstate and all magnified ×200 000.* **(a)** *Whole virus particle (D antigen) ca. 30 nm in diameter and displaying a hexagonal profile.* **(b)** *High concentration of virus in hexagonal array.* **(c)** *Freeze-dried virus with low angle platinum shadowing (print reversed to give black shadows); virus particles produce either pointed or blunt-ended shadows, which are consistent with an icosahedral particle.* **(d)** *Penetration of stain into empty particles reveals outer capsid.* **(e)** *Empty particles (C antigen) showing small central unstained portions representing incomplete contents.* **(f)** *Flattened particles showing complete contents and outer capsid.* **(g)** *Flattened particles showing breakdown of capsid into angular or crescentlike portions.* **(h and i)** *Particles heated at 56°C for 2 min produce aggregates of ca. 12 crescentlike or circular structures.*

staining methods. Figure 3 demonstrates some of the features of poliovirus, but similar results would be obtained with all picornaviruses. The viruses are 25–30 nm in diameter (Figure 3a), and can occasionally present a hexagonal appearance (Figure 3a) or form hexagonal arrays (Figure 3b). Similarly, shadowed preparations can produce blunt-ended or pointed shadows, consistent with an icosahedral structure (Figure 3c). In preparations positively stained after drying of the virus from ethanol where the RNA is extruded, the capsid may remain negatively stained and so the thickness of the virion wall can be seen to be ca. 2.5 nm. A similar thickness has been determined for the empty capsids, which are in general penetrated by negative stain (Figure 3d), although frequently there are regions from which the stain is excluded (Figure 3e). When the particle is distorted during drying, it may expand and break into circular or crescent-like portions (Figure 3g). Similarly, heating (Figure 3h, i) can give rise to 12 crescentic or circular structures, which are believed to correspond to the pentamers of the icosahedron.

Understanding of picornaviruses was extended immensely by the determination of the atomic structures of rhinovirus 14 (Rossmann et al. 1985), the type 1 poliovirus strain Mahoney (Hogle et al. 1985), the cardiovirus mengo virus (Ming et al. 1987) and FMDV (Acharya et al. 1989). The structure of the type 1 poliovirus strain Mahoney is shown in Figure 4. Although all picornavirus structures solved to date are strikingly similar to each other, and to the spherical plant viruses such as southern bean mosaic virus and tomato bushy stunt virus, there are also clear differences between them.

The capsid of poliovirus is composed of 60 protomers, each being made up of one molecule of each of the four virion proteins VP1, VP2, VP3, and VP4. The protomers are arranged with icosahedral symmetry. Each of the 20 faces of the icosahedron is made up of three protomers, orientated so that the 12 apices of the icosahedron are occupied by five copies of VP1 while the center of each face is occupied by three copies each of VP2 and VP3, alternating around the threefold axis of symmetry. The overall thickness of the shell is about 3 nm, extending

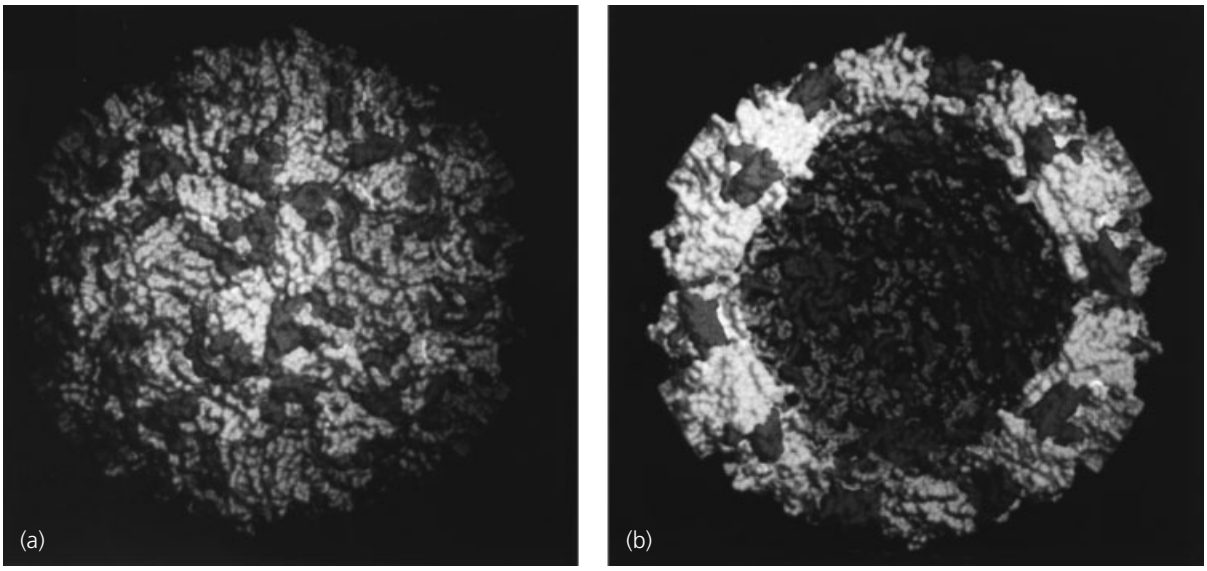

Figure 4 *Structure of the Mahoney strain of type 1 poliovirus showing* **(a)** *the complete capsid, and* **(b)** *the capsid with one pentamer removed to reveal the inside of the virion.*

11–14 nm from the particle center. However, the apices of the icosahedron and the face at the threefold axis of symmetry form two elevated features separated by a cleft or 'canyon' that circles the apex, which, for the enteroviruses and rhinoviruses, is believed to be the site by which the virus attaches to the specific receptor site on the cell.

The structural organization of the individual proteins that make up the virion is similar, (Figure 5). Each protein has a wedge-shaped core structure composed of eight strands of protein, shown as broad arrows in Figure 5, arranged in an antiparallel β-sheet array, the eight strands collectively forming a barrel (termed the β barrel). The core structure of polioviruses, rhinoviruses, and other spherical viruses, including plant viruses, are very similar in this respect. The features that are unique to the individual virus, including antigenic sites, arise from the loops that join the different β strands and the sequences at the N and C termini.

The narrow end of the β barrel of VP1 is located near the icosahedral apex of the virus while the corresponding regions of VP2 and VP3 alternate around the threefold axis of symmetry. VP4 forms a lattice around the inside of the pentameric apex. Interactions between adjacent pentamers include regions of secondary structure in the form of β sheets between the β barrels of VP2 and VP1.

In addition to the protein components of the virus shell, the N terminus of each VP4 protein is covalently bound to a myristic acid residue (Chow et al. 1987). The myristate sequences penetrate the pentameric apex, possibly forming a framework for assembly.

The structures of poliovirus and rhinovirus are very similar but differ from that of the cardioviruses, typified by mengo virus (Ming et al. 1987), where the pentameric apex is surrounded by five distinct pores rather than a canyon. The 15 C-terminal residues of VP1 are disordered but exposed on the virus surface, whereas all C-terminal residues of VP1 are ordered in the poliovirus and rhinovirus.

The particle shell of FMDV is relatively smooth because of the truncation of certain loops, and there is no canyon or series of pits around the pentameric apex (Acharya et al. 1989). One loop in VP1 forms a disordered surface structure known to be a major antigenic site. The C terminus of VP1 is also a disordered surface feature lying in the region of the disordered loop. A residue in VP2 is covalently linked by a disulfide bridge to a residue in the disordered VP1 loop, and is therefore itself faint in the structure. It is believed that the highly exposed, disordered loop forms the site on the virus by which it attaches to the host cell, in contrast to the other picornaviruses which attach to the cell via the canyon or pit regions.

Genome structure and function

Sequences of the genomes of many picornaviruses representing strains from each genus have been determined. The genomic RNA, constituting about 33 percent of the mass of the virion, varies in size from about 7 200 nt for rhinovirus to 8 500 nt for FMDV (mol. mass 2 000–3 000 kDa). Virion RNA is of messenger sense and therefore infectious for cells, although less so than intact virus. The layout of the genome of poliovirus is presented in Figure 6. The 5′ terminus of the RNA is covalently linked to a small protein (VPg) of 22 amino acids via the phenolic hydroxyl group of the tyrosine at residue 3 from the N terminus, a residue conserved in all picornaviral sequences of VPg to date. The following 740 nucleotides of the RNA constitute the 5′ noncoding region preceding the coding region of the genome,

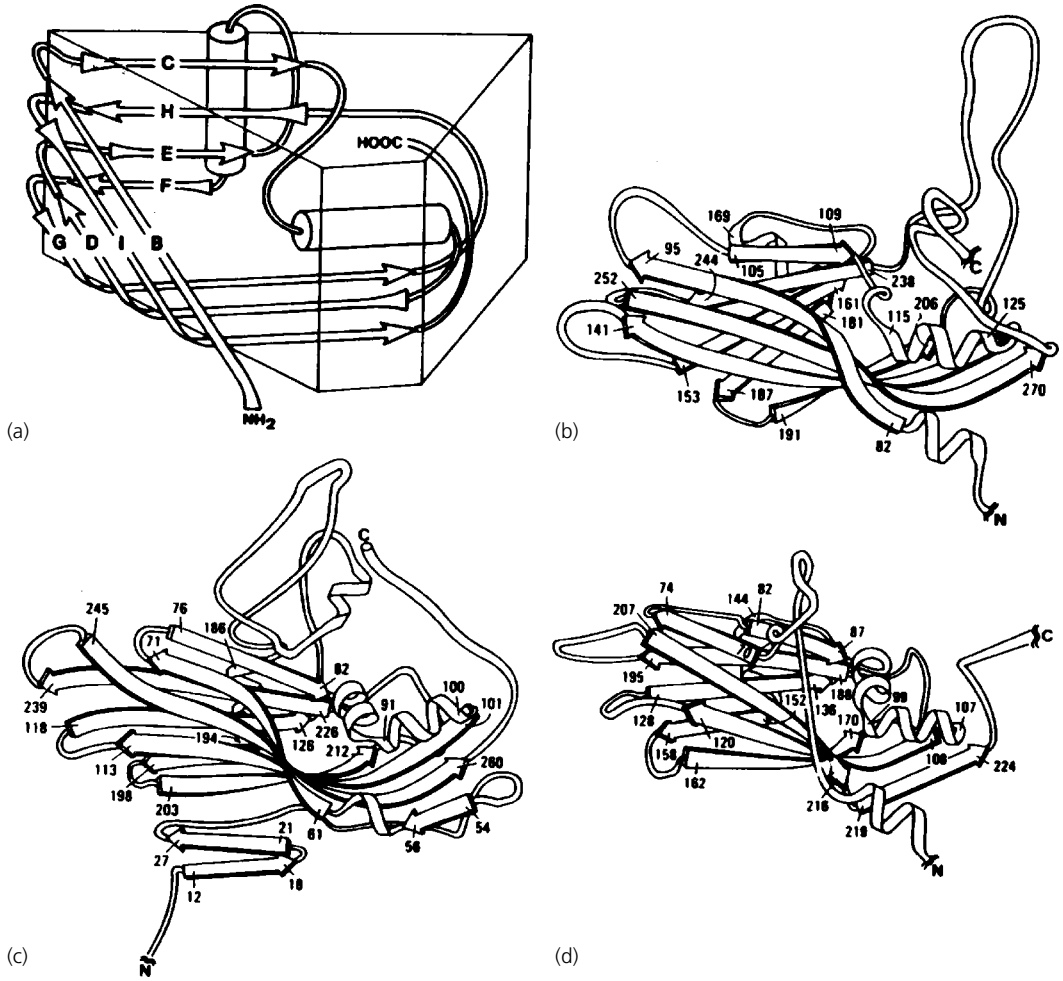

Figure 5 *Structure of the proteins making up the poliovirus capsid:* **(a)** *schematic diagram of β-barrel structure (arrow) and connecting α helices (cylinders);* **(b)** *VP1;* **(c)** *VP2;* **(d)** *VP3.*

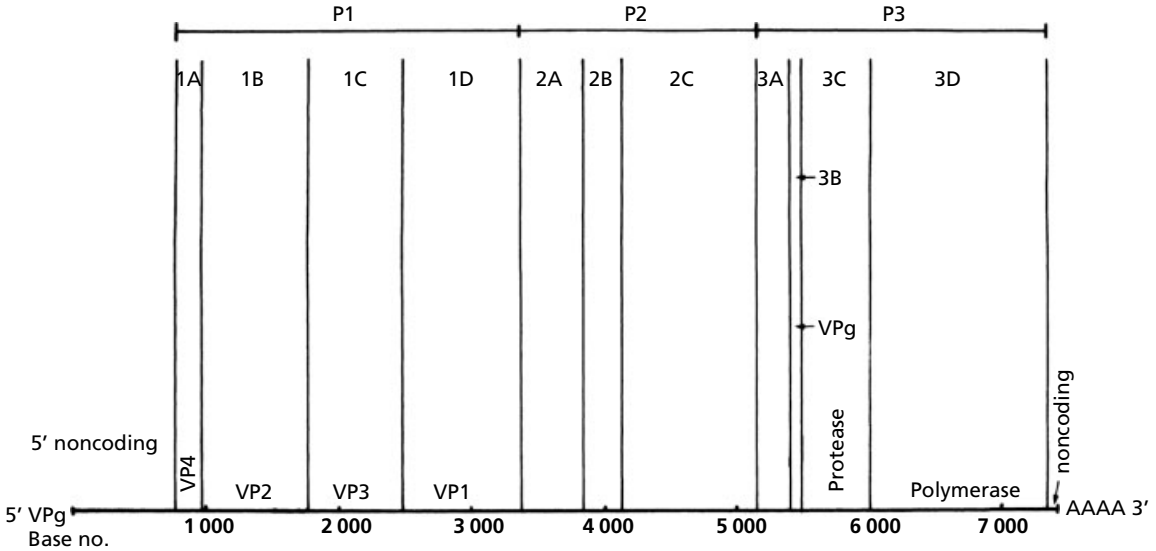

Figure 6 *Organization of the genome of enteroviruses showing the 5′ and 3′ noncoding regions and the location of the regions coding for the various proteins. Nomenclature is according to Rueckert and Wimmer (1984) and the common name where appropriate.*

which is translated as a single large protein cleaved by virus-encoded proteases as it is translated and post-translation. The genome terminates in a short untranslated 3′ noncoding region of about 70 nt, to which a sequence of 40–100 adenosine residues is attached, comparable to that found on many eukaryotic mRNAs. Sequence analysis of viral proteins has defined the genomic location and proteolytic cleavage sites used in processing. The structural proteins are encoded in the order VP4, VP2, VP3, and VP1, or 1A, 1B, 1C, 1D in the formal nomenclature (Rueckert and Wimmer 1984), from the 5′ end, making up the P1 region of the polyprotein which is excised as a single unit during replication. The nonstructural proteins P2, consisting of proteins 2A, 2B, and 2C, and P3, consisting of proteins 3A, 3B, 3C, and 3D, are also considered to be single units. The rhinoviruses closely resemble the enteroviruses except that the 5′ noncoding region lacks the poorly conserved 100 nt region immediately preceding the open reading frame.

The genomic organization of the cardioviruses and aphthoviruses differs from this general structure in that they encode a leader protein (L) before the P1 region and contain a polycytidylate tract in the 5′ noncoding region. In addition, protein 2A of FMDV is very small, and the genome includes three distinct copies of the protein VPg, any of which may be covalently linked to virus-derived RNA.

Complete cDNA copies of the picornavirus genome can be generated and used either to recover infectious virus directly from the DNA (Racaniello and Baltimore 1981) or, after linking to transcription systems such as SP6 or T7, to generate infectious RNA. It is thus possible to study the effect of defined genetic manipulations on the phenotype of the virus. For technical reasons, complete infectious copies of aphthovirus or cardiovirus genomes are more difficult to produce than those of the other genera.

Antigens

Most studies of the antigenic properties of enteroviruses, and of poliovirus in particular, have been concerned with humoral immunity to structural proteins, which is believed to be the major factor in protection from disease, although some work has concerned sites involved in recognition by T cells (Mahon et al. 1995). In infection by FMDV, however, a major immune response is directed against the infection-associated antigen (IAA) which has been shown to correspond to the nonstructural RNA polymerase protein 3D.

Antigenic differences may occur between different isolates; for example, isolates of type 3 polioviruses in Finland during 1984/85 differed from classic type 3 strains (Huovilainen et al. 1987) and UK strains of coxsackie virus B5 from 1973 were very different from the coxsackie virus Faulkner strain isolated in 1952.

The infectious virus particles of polioviruses and other picornaviruses differ antigenically from the empty capsids. Mayer et al. (1957) resolved poliovirus preparations into distinct fractions by centrifugation on a sucrose step gradient; most of the infectious material appeared in the fourth layer (D) and reacted preferentially with convalescent sera, but viral antigens could also be detected in the lighter third layer (C) which reacted preferentially with acute phase sera. D antigenic material corresponds to infectious particles, and C to empty capsids. Others showed that the natural virus expressed one antigenic determinant (termed N antigen), whereas material heated at 56°C for 30 minutes expressed another (H antigen) (Hummeler and Tumilowicz 1960); in general, N and D antigens are equated, as are C and H antigens. Relatively mild treatments have a pronounced effect on antigenicity (Le Bouvier 1955). Rhinoviruses also exhibit D and C antigen characteristics (Butterworth et al. 1976).

Monoclonal antibodies derived from mice immunized with poliovirus can bind to the D or to the C antigenic forms of the virus (Rombaut et al. 1983), or to both (Ferguson et al. 1984). In addition, some D-specific antibodies bind to subunits that are precursors to virions in the assembly pathway, whereas others bind only to mature virus. The particular sites recognized by antibodies were identified by generating antigenic mutants resistant to neutralization by monoclonal antibodies (Minor et al. 1986a; Page et al. 1988).

The specific amino acid substitutions found in antigenic mutants of poliovirus selected with murine antibodies are largely located in the loops decorating the β barrels and clustered into several non-overlapping sites on the surface of the virion. The regions in which mutations have been identified are shown in Table 3, and each site is complex and conformational in nature. For poliovirus of both type 2 and type 3, site 1 seems to be the major target of the murine immune response, whereas antibodies against the corresponding region of type 1 have not been induced by immunization with native virus.

Antibodies directed against site 3 of poliovirus serotypes 1 and 3 tend to be highly strain specific, even to the extent that antigenic drift can be demonstrated during the period of excretion by vaccinees.

Neutralizing antibody is difficult to induce with isolated viral proteins or with short peptides based on sequences found within them except where, as in FMDV, the immunogenic sequence is disordered in the structure (Bittle et al. 1982). The difference is attributable to the highly integrated and conformational nature of the antigenic sites. Even where viruses have been constructed in which entire sites have been exchanged between different serotypes (Burke et al. 1988; Murray et al. 1988) and can have antigenic and immunogenic properties of both parents, the inserted site is imperfectly expressed (Minor et al. 1990, 1991). The viruses usually grow poorly.

Table 3 *Antigenic sites for the neutralization of poliovirus and Rhinovirus by monoclonal antibodies*

Poliovirus			Rhinovirus 14		
Site	**Amino acids involved**		**Site**	**Amino acids involved**	
1	VP1	89–100	Nim 1a	VP1	91, 95
	VP1	142	Nim 1b	VP1	83, 85, 138, 139
	VP1	166	. . .	. . .	. . .
	VP1	253	. . .	. . .	. . .
2	VP1	220–222	Nim II	VP1	210
	VP2	164–170	. . .	VP2	158, 159, 161, 162
	VP2	273	. . .	. . .	. . .
3	VP1	286–290	Nim III	VP1	287
	VP3	58–60	. . .	VP3	72, 73, 75, 78, 203
	VP3	70–72	. . .	. . .	. . .
4	VP3	77–80	. . .	. . .	. . .
	VP2	72	. . .	. . .	. . .

Similar antigenic studies have been performed for rhinovirus 14. Sherry and colleagues (1986) identified four antigenic sites recognized by monoclonal antibodies (Table 3). All are surface features and in general the antigenic structures identified in all picornaviruses correspond to all of the prominent surface features in the structure, which are usually loops between strands of β barrels (Minor 1990). In contrast to poliovirus, no sites are strongly immunodominant or recessive.

When virus infection is initiated, the capsid undergoes a major rearrangement with the extrusion of the N terminus of VP1, which is normally internal. Antibodies to this region have been described in post-infection human sera and are believed to have neutralizing capacity.

Replication

ENTRY INTO HOST CELLS

Viral RNA from poliovirus is able to induce a single round of replication in rabbit kidney cells, which are not normally susceptible to infection (Holland et al. 1959), indicating that the blockage is at the level of virus entry. Saturable receptors have been demonstrated (Lonberg-Holm et al. 1976) and competition experiments showed that the three serotypes of poliovirus attach to the same site, distinct from that used by other enteroviruses. Monoclonal antibodies directed against cellular components have been raised that specifically block the binding of poliovirus (Minor et al. 1984), coxsackie viruses (Campbell and Cords 1983), and rhinovirus 14.

The gene coding for the poliovirus receptor was identified by Mendelsohn et al. (1986, 1989). It is a three-domain protein of the immunoglobulin superfamily with an unglycosylated molecular mass of 42 kDa. The cellular receptor for most rhinoviruses is the cell adhesion protein ICAM-1, a five-domain protein of the same superfamily (Greve et al. 1989; Staunton et al. 1989).

Other picornavirus receptors identified include decay accelerating factor (DAF), implicated in the complement pathway as the receptor for echovirus 7, among others (Ward et al. 1994) and integrin VLA2 for echovirus 1 (Bergelson et al. 1992). The possible need for additional molecules in attachment or penetration is suggested by the failure of mouse cells transfected with the genes for either ICAM-1 or DAF to support the growth of rhinovirus 14 or echovirus 7. Moreover, whereas mouse cells transfected with the poliovirus receptor are highly susceptible to poliovirus (Pipkin et al. 1993), it has been suggested that CD44 may also play a role (Shepley and Racaniello 1994). The poliovirus receptor and susceptibility to coxsackie virus B3 and echovirus 11 have been shown to be encoded on human chromosome 19 (Medrano and Green 1973; Miller et al. 1974). Transgenic mice carrying the gene for the human poliovirus receptor are susceptible to poliovirus infection by a variety of routes, developing paralysis similar to that seen in primates (Ren and Racaniello 1992) and such animals have been extensively used in pathogenesis studies in place of primates. A summary of the receptor sites used by some picornaviruses is given in Table 4, but the situation is complex except for polio in that the receptor sites listed alone do not in general confer susceptibility when transfected into nonsusceptible cells alone (Rieder and Wimmer 2002).

UNCOATING

When virus is allowed to bind to cells at room temperature and the cultures are then incubated at 37°C, up to 90 percent of the virus may be released into the medium. The released virus (A particles) has lost VP4, and has converted from D (N) antigenicity to C (H) antigenicity, although it retains the virion RNA (Joklik and Darnell 1961). Similar particles can be identified in the cells, and their production can be catalyzed by soluble receptor in the case of poliovirus.

PROTEIN SYNTHESIS

The genomic RNA is infectious and translated into virion proteins directly. The 5′ terminus of many

Table 4 *Receptors and accessory factors used by picornavirus genera and species*

Genus	Species	Receptor	Accessory factors
Enterovirus	**B**		β_2–m

eukaryotic mRNA species is blocked by a 'cap' or 7-methylguanosine residue linked in the reverse orientation to the 5′ terminal residue by phosphate groups. Ribosomes bind close to the free capped 5′ end of the RNA and then 'scan' the sequence for the first suitable initiation codon (defined in part by the nucleotides that flank it) at which protein synthesis commences. Picornavirus RNAs are translated by another mechanism in which the 5′ noncoding region acts as an internal initiation site for translation not requiring a free terminus (Pelletier and Sonenberg 1988). Following the initiation of viral protein synthesis, host protein synthesis is rapidly shut off by mechanisms that are not fully understood but include the proteolytic cleavage of initiation factors required for the cap-dependent protein synthesis of the host cell by a mechanism involving the virus-coded protease 2A.

POST-TRANSLATION PROCESSING

The proteases of polioviruses and other enteroviruses are extremely specific and have been proposed as possible targets for chemotherapeutic agents. In the case of poliovirus, the P1 protein comprising all the structural proteins is excised as a single unit by protease 2A, which cleaves between a tyrosine–glycine pair. This has the effect of removing the structural from the nonstructural proteins before they are processed any further. The corresponding protease in coxsackie virus B3 is believed to cleave between a threonine–isoleucine pair. Later processing is carried out by protease 3C or the precursor molecule 3CD. It may be difficult to identify the active moiety, which may be an intermediate or a final product of the cleavage pathway. The processing protease in poliovirus cleaves between glutamine–glycine pairs, including those found in the P1 region between VP2 and VP3, and VP3 and VP1. The exposure and possibly the amino acid sequence surrounding the dipeptide govern whether cleavage occurs, as many such pairs are not cleaved. A similar sequence specificity seems to function in coxsackie virus B viruses, but the situation is less clear in viruses such as hepatitis A virus, or other picornaviruses, such as EMC, in which cleavage does not seem to involve a specific dipeptide (Palmenberg 1987).

Two further proteolytic cleavages take place in the viral growth cycle. One occurs in protein 3D, at a tyrosine–glycine pair, and is thus probably performed by protein 2A. This may have the effect of reducing the amount of active polymerase in the cell, but the advantage of this is not understood, especially as at least the Sabin type 3 vaccine strain of poliovirus and viruses related to it do not carry out this step, although they grow to high titer in vivo and in vitro. The final cleavage involves the formation of VP2 and VP4 from the precursor VP0, which occurs as the last stage of maturation.

REPLICATION OF RNA

The synthesis of RNA requires an RNA template that is read from the 3′ to 5′ direction, whereas protein synthesis requires an RNA template read in the opposite direction. The two processes are therefore mutually exclusive, and the factors influencing the fate of a particular RNA molecule are not known.

The replication of poliovirus RNA requires the synthesis of both negative and positive strands of RNA (Kuhn and Wimmer 1987; Paul 2002). Messenger-sense (positive-strand) RNA is synthesized in a great excess over the complementary-sense RNA. Infected cells contain complete double-stranded copies of one positive and one negative strand of viral RNA, termed replicative forms (RF) and partial double-stranded structures termed replicative intermediates (RI). All nascent strands of polio RNA of either sense are covalently linked to VPg at the 5′ terminus. This protein is absent from RNA associated with ribosomes. The association of VPg with nascent RNA presumably accounts for the fact that inhibitors of protein synthesis, such as puromycin, rapidly inhibit RNA synthesis.

All of the nonstructural proteins are involved in RNA replication in some way. Viral protein 3D is present in replication complexes isolated from infected cells (Lundquist et al. 1974) and is able to synthesize poly(U) from a poly(A) template if primed with oligo(U) (Flanegan and Baltimore 1977). Protein 3B (VPg) is associated with nascent RNA strands. Guanidine inhibits poliovirus RNA synthesis, and mutants that are either resistant to it or dependent on its presence for growth possess base changes in protein 2C, which is therefore also implicated in synthesis in some way. This protein may influence host range in polioviruses and in rhinoviruses. It is therefore likely that some host factor is involved, although this could, for example, involve structural factors contributed by the host, such as cell membranes.

The detailed mechanism of viral RNA synthesis is controversial, although it is accepted that it occurs in particulate or membranous regions of the infected cell. Replication of virus in vitro has been reported in protein translation systems primed with polioviral RNA. Protein 3D is the main component of replicative complexes which may be prepared from infected cells by mild detergents. Such complexes synthesize both virion (+) and complementary (−) sense RNAs in vitro. Three models for RNA synthesis have been put forward.

1. Dasgupta et al. (1980) reported the presence of a 67 kDa protein able to initiate viral RNA synthesis in the absence of oligo(U). The protein has kinase activity, and the implication of host proteins in viral nucleic acid synthesis in other systems is well documented. However, this factor [host factor (HF)] leaves no clear role for VPg.
2. Flanegan and co-workers (Young et al. 1985) have reported a host enzyme-terminal uridylate transferase (TUT) – which is able to add uridine residues to the 3′ termini of viral nucleic acid. Uridine bases added to the 3′ end of the virion RNA that carries a poly(A) tail would form a tail that could loop back and anneal to the poly(A) sequence as a primer for 3D. The 3′ terminus of the complementary RNA is UUUUAA, so there is a short sequence for such a hairpin structure to form and prime RNA synthesis on the negative-sense RNA. An analogous mechanism has been suggested in the replication of parvoviruses. The hairpin structure would be cleaved by VPg or a precursor, in the course of which VPg would be transferred to the 5′ end of the nascent strand.
3. There is a proposal that uridine residues are added to VPg to make VPg pUpU, which then functions as a primer. Such an intermediate has been reported.

Combinations of these models have been proposed and the reader is referred to Paul (2002) for further details and discussions of the experimental evidence available.

ASSEMBLY OF CAPSIDS

The structural proteins are synthesized and processed as a unit and assemble to form pentamers of VP0, VP1, and VP3 (Putnak and Phillips 1981). Isolated pentamers (or 14S particles) are able to assemble into procapsids, which are complete but empty viral shells, sedimenting at 75S. It is possible to prepare soluble fractions from infected cells containing 14S subunits able to assemble to give 75S empty shells. If the pH is allowed to fall, however, the 75S units become altered, adopting the C antigenic form, and are no longer dissociable.

The last step in the maturation of the infectious virion is the cleavage of VP0 to give VP2 and VP4. It has been proposed that this occurs autocatalytically by insertion of the nucleic acid as a proton donor in the presence of a serine residue at position 10 of VP2 close to the cleavage point (Rossmann et al. 1985). However, specific mutagenesis of residue 10 does not prevent cleavage of VP0. A possible model for virion assembly is that the empty 75S capsids act as a dissociable reservoir of structural proteins. As the units reassociate around the genomic RNA, the cleavage of VP0 to VP2 and VP4 occurs, making assembly essentially irreversible under

the conditions pertaining in the infected cell. This scheme remains speculative but plausible.

Effects on host cells

Replication of enteroviruses is normally accompanied by apoptosis of the host cell. The viruses almost certainly encode proteins that affect this process, but this remains a subject of study. Non-lytic persistent virus infections have been reported for poliovirus (Sarnow et al. 1986), hepatitis A virus, echovirus 6, and the coxsackie virus B viruses (Matteucci et al. 1985) in appropriate cells. There is evidence for the persistent enterovirus infection in vivo of humans and rats (Bowles et al. 1986; Schnurr and Schmidt 1988; Yousef et al. 1988).

Resistance to physical and chemical agents

Enteroviruses can remain viable for years at −20°C and −70°C, and for weeks at 4°C, but lose infectivity slowly at room temperature and with increasing rapidity as the temperature is raised. Their inactivation at all environmental temperatures is inhibited by molar magnesium chloride; this property has led to the widespread use of magnesium chloride as a stabilizer of oral poliovaccine.

In the absence of organic matter, enteroviruses are rapidly inactivated by ultraviolet light and usually by drying.

Enteroviruses are insensitive to alcoholic and phenolic disinfectants, ether, chloroform, and deoxycholate. Treatment with formaldehyde (0.3 percent), 0.1 M HCl, or free residual chlorine (0.3–0.5 p.p.m.) causes rapid inactivation. The activity of chlorine is diminished by a high pH, low temperature, and the presence of organic matter, and it may therefore be less effective when used under field conditions.

CLINICAL AND PATHOLOGICAL ASPECTS

Enteroviruses

The alimentary tract is the predominant site of replication of enteroviruses. Although infection is usually asymptomatic, enteroviruses are recognized causes of paralytic poliomylitis, encephalitis, aseptic meningitis, myocarditis, conjunctivitis, and numerous other syndromes associated with target organs outside the alimentary tract. The serotypes comprising each group and the main disease caused by them are listed in Table 1.

HOST RANGE

The only natural host of polioviruses are humans, although most strains will infect Old World monkeys and chimpanzees. However, cotton rats, mice and hamsters, and fertile hens' eggs may be infected by strains adapted in the laboratory. Other enteroviruses, notably the coxsackie viruses, will infect mice under laboratory conditions. Swine vesicular disease virus (SVDV) is closely related to coxsackie virus B5.

PATHOGENESIS

Enteroviruses infect via the mouth or oropharynx. The incubation period is usually 7–14 days, with extremes of 2–35 days. Virus infects the mucosal tissues of the pharynx, gut or both, finally entering the bloodstream and gaining access to cells of the reticuloendothelial system and specific target organs such as the meninges, myocardium, and skin. Enteroviruses can generally be recovered from the pharynx during the first week of illness and from the feces for 1–4 weeks after onset of illness; they have been isolated from cerebrospinal fluid (CSF), spinal cord, brain, heart, conjunctivae, and skin lesions.

Two or more enteroviruses may propagate simultaneously in the alimentary tract but usually multiplication of one virus interferes with the growth of the heterologous type.

Poliomyelitis

Poliomyelitis is the most serious disease caused by any of the enteroviruses. According to one view (Bodian 1955), the virus first multiplies in the tonsils and Peyer's patches of the small intestine before spreading to the more distant lymph nodes and thence by a viremia to other sites, including the spinal cord. According to another view (Sabin 1955), the virus multiplies at mucosal surfaces and accumulates in the draining lymph nodes where some, but not all, strains may replicate. From there virus seeds peripheral sites, including peripheral nerves, and the virus generated at the distant sites is the source of the detectable viremia. Antibodies appear early and are protective even when given as passive immunoglobulin (Hammon et al. 1953).

Virus may pass to the spinal cord along nerves under certain conditions; for example, in children with inapparent infection either at the time of tonsillectomy or at the time of injection with material causing local inflammation.

The anterior horn cells of the spinal cord are most readily infected by poliovirus, but in severe cases the intermediate gray ganglia and even the posterior horn and dorsal root ganglia may also be involved. In the brain, the reticular formation, the vestibular nuclei, the cerebellar vermis, and the deep cerebellar nuclei are most often affected.

Other enteroviruses

The pathogenesis of nonpolio enteroviruses is similar to that of poliovirus in the initial stages but the target

organs vary. For example, echoviruses 6 and 9 may infect the CNS, causing meningitis. Coxsackie virus A7 and enterovirus 71 can cause paralysis, and others, such as coxsackie virus B viruses, may infect the heart or muscle.

Coxsackie virus A24 and enterovirus 70 resemble rhinoviruses, being spread by fomites and direct inoculation of the conjunctiva by contaminated fingers. The incubation period is very short (12–48 hours); recovery is usually complete within 1–2 weeks.

HOST FACTORS

Age is an important determinant of the severity of enterovirus disease, the incidence of some syndromes being greatest in neonates (e.g. myo- or pericarditis).

Malnutrition may worsen disease. When marasmus was induced in normally resistant postweaning mice, challenge with coxsackie virus B3 gave more severe disease.

Physical exertion while incubating poliovirus infection is associated with a higher incidence or greater extent of paralysis. The severity of paralysis is increased in monkeys infected experimentally with poliovirus and made to swim until exhausted. Similarly, exercising mice infected with coxsackie virus A9 or coxsackie virus B3 results in increased virus titers in their myocardium, in higher mortality rates, or both.

Pregnancy and parturition may be associated with a greater risk of paralysis with poliovirus infection or a greater risk of myocarditis with coxsackie virus B infection. Hypo- or agammaglobulinemic individuals with impaired or absent B-cell function but normal T-cell function clear enterovirus infections more slowly than those with a normal immune system. This provides further evidence for the importance of humoral immunity in the control of enteroviral infection. Maternal antibody may not protect from infection but will prevent disease.

CLINICAL SYNDROMES

The description of clinical syndromes below is not exhaustive. Further details concerning enteroviral diseases may be found in reviews by Moore and Morens (1984); Melnick (1990), and Bendinelli and Friedman (1988).

Most enterovirus infections produce clinically inapparent or minor illness. The consequences of infection, when they do occur, range from specific clinical syndromes, such as fatal paralytic or cardiac illness, to minor undifferentiated febrile illnesses. Asymptomatic infection rates are reported as 90–95 percent for the polioviruses, 76 percent for the coxsackie viruses and 43 percent for the echoviruses.

Poliomyelitis

Exposure to poliovirus may have the following consequences:

- **inapparent infection** (90–95 percent)
- **'abortive'** or **'minor' illness** (4–8 percent) with symptoms of upper respiratory tract infection, gastrointestinal upset, or influenza-like illness. The patient recovers within a few days
- **non-paralytic poliomyelitis** (1–2 percent), an illness of about 2–10 days similar to 'aseptic' meningitis, often accompanied by back pain and muscle spasm. Recovery usually is rapid and complete
- **paralytic poliomyelitis** (0.1–2 percent). The major illness, paralysis, usually follows a prodromal illness similar to the minor illness described above, especially in children. Thereafter the predominant feature is flaccid paralysis resulting from lower motor neuron damage. Paralytic poliomyelitis is termed **spinal** if the lower spine is involved or **bulbar** (from 'bulb' or medulla oblongata) if the upper spine and brainstem are involved. Bulbar poliomyelitis is the more serious because it affects the respiratory system.

A paralysed patient may recover completely or have varying degrees of residual deficit. A review of 203 cases between 1969 and 1981 in the USA (Moore et al. 1982) showed that residual paralysis was minor in 11 percent and significant or severe in 79 percent; 10 percent of the cases were fatal.

Post-polio syndrome has been described in which individuals who have survived an initial attack suffer a degeneration of function many years later. This may be anatomic in origin as advancing age results in the loss of nerve cells from an already damaged pathway. Sequences of enterovirus-related nucleic acid have been reported in the CSF of such cases, however, and some workers believe that the virus may persist.

'Aseptic' meningitis

Nonbacterial 'aseptic' meningitis (AM) is a common manifestation of enterovirus infection. Pleocytosis of the CSF is characteristically lymphocytic but may show transient predominance of polymorphonuclear leukocytes when cell counts are high in the early stage of illness, temporarily mimicking bacterial meningitis. Recovery is usually complete within a few weeks, although irritability and fatigue may persist for some weeks and there is a small risk of serious neurological damage in the first year of life (Wilfert et al. 1981). Second attacks of AM may occur from infection with other serotypes.

Paralytic disease

Polioviruses have been the dominant viral cause of paralysis in most of the world but are approaching eradication as described later. Sporadic cases of paralysis associated with coxsackie virus A7 continue to be reported (Gear 1984).

Paralysis has also been reported in association with coxsackie viruses B2–6 and echovirus types 3 (transverse myelitis), 4, 6, 9, 11, and 19.

Enterovirus 71 is capable of causing severe CNS disease with persisting flaccid paralysis, although it can also cause meningitis, encephalitis, and hand-foot-and-mouth disease (HFMD), depending on the outbreak (Melnick 1984).

Enterovirus 70, an agent of acute hemorrhagic conjunctivitis (AHC), has caused poliomyelitis-like illness (Kono et al. 1977).

Encephalitis

The dominant enterovirus associated with outbreaks of encephalitis is enterovirus 71, although poliovirus, coxsackie viruses A9, B3, B5, and B6 and echoviruses 6, 9, 17, and 19 have all been isolated from CSF or brain tissues.

Myalgic encephalomyelitis (postviral fatigue syndrome)

Multiple symptoms are associated with this illness (Behan 1980), but always include extreme muscle fatigue following slight physical effort, muscle pain, and psychological upset. The lack of objective physical signs, pronounced emotional lability, and neuroticism and the unknown nature of the disorder have made it easy for some physicians to dismiss the illness as hysterical. Myalgic encephalomyelitis (ME) is not a fatal disease but recovery may take months or years; relapses during periods of physical or mental stress are common. Chronic infection with enteroviruses has been reported (Yousef et al. 1988).

Pleurodynia (Bornholm disease)

The group B coxsackie viruses are the main identified causes of pleurodynia, also known as Bornholm disease, epidemic myalgia, or the devil's grippe. The chest pain is spasmodic, intensified by movement and may be severe. Abdominal pain resulting from involvement of the diaphragm occurs in approximately half the cases; in children this may be the chief complaint. The illness lasts for 2–14 days and is self-limited; recovery is complete although short relapses are common.

Sporadic cases of pleurodynia have also been associated with coxsackie viruses A4, A6, and A10; coxsackie virus A9 has been implicated in this syndrome and also in chronic diseases of the muscle and joints.

Congenital and neonatal infection

Prematurity, low birth weight, onset of illness within the first few days of life, occurrence during the 'enterovirus season' and recent antepartum or postpartum febrile illness in the mother are risk factors for the most severe, generalized and fatal neonatal enteroviral disease, most commonly associated with the coxsackie virus B, particularly coxsackie virus B2, and coxsackie virus B4. Neonatal illness has seldom been attributed to coxsackie virus A viruses but echoviruses (e.g. echoviruses 4, 9, 11, 17–20, 22, and 31) have been incriminated in both nursery outbreaks and sporadic infections. Fatal cases of echovirus infection generally present with progressive severe hepatitis and CNS involvement, whereas fulminant coxsackie virus B infections can be distinguished by the presence of severe myocarditis.

Cardiac disease

Severe myocarditis is usually a prominent feature of disseminated enterovirus infections of neonates; less severe myocarditis or pericarditis may follow infection of older children and adults. It has been estimated that ca. 5 percent of all symptomatic coxsackie virus infections induce heart disease.

Nucleic acid hybridization has been used to detect enterovirus RNA in myocardial biopsies. Replicating enterovirus RNA was found in 19 of 81 patients with suspected myocarditis (Kandolf 1988) but in none of the controls. Endomyocardial biopsies from >100 patients with heart muscle disease were investigated by Archard et al. (1988). Enterovirus genomic RNA was detected in 60 percent with active myocarditis and 47 percent with healing myocarditis; tissue from cases of other specific heart muscle diseases was consistently negative. All patients who made a coxsackie virus B-specific IgM response also had detectable enterovirus RNA in biopsy tissue. Enterovirus-infected myocardial cells have also been detected by hybridization in situ in dilated myocardiomyopathy (Kandolf 1988). Persistence of enteroviral genomes may therefore be implicated in chronic heart disease.

Mucocutaneous syndromes

Herpangina Herpangina is characterized by fever and a vesicular exanthem that typically involves the fauces and soft palate. It is chiefly associated with coxsackie virus A types 1–10, 16, and 22, and less commonly with coxsackie viruses B1–5 and some echoviruses. The disease occurs during the summer season and generally involves clusters of patients. Herpangina mainly affects young children but occasionally is seen in young adults. The illness is self-limited, with recovery in a few days.

Hand-foot-and-mouth disease (HFMD) HFMD is predominantly a childhood illness, usually associated with infection by coxsackie virus A16 or enterovirus 71. Occasionally, cases due to coxsackie viruses A5, A7, A9, A10, B2, and B5 have been reported. Typical cases of HFMD have vesicles and ulcers mainly in the front of the mouth, most frequently on the tongue, and a vesicular exanthem, mostly localized on the palms and soles;

virus can be isolated readily from these sites. During outbreaks, ca. 60–70 percent of cases show the complete clinical picture of HFMD. Recovery from HFMD is usually complete within 1–2 weeks.

Swine vesicular disease (SVD) in humans Swine vesicular disease virus (SVDV) is a porcine enterovirus that is closely related to coxsackie virus B5 (Zhang et al. 1993). The disease in pigs was first recognized in Italy in 1966. Since then SVD has been seen throughout Europe as well as in Hong Kong and Japan. The lesions in pigs resemble those caused by foot-and-mouth disease and other vesicular diseases of pigs. No vesicles have been seen in workers with pigs affected with SVD although, in laboratories, inapparent human infection has occurred and antibodies have been detected. There are on record four human cases with presumptive evidence of infection with SVDV. One patient had a severe illness with fever, myalgia, weakness, and abdominal pain, in two the disease was mild and the fourth had meningitis. In three of these patients infection occurred after exposure to pigs; the other was exposed to the virus in the laboratory.

Exanthems Usually transient and erythematous (rubelliform, maculopapular, rarely morbilliform, or vesicular) exanthems have been reported in infections by enteroviruses, notably during outbreaks of infection with coxsackie viruses A9, A16, and B5 or echoviruses 4, 9, and 16. Rash is seldom the sole clinical feature in symptomatic enterovirus infections. Fever, malaise, cervical lymphadenopathy, and aseptic meningitis may also occur in patients with rash. Rashes associated with coxsackie virus A9 and echovirus 9 can mimic rubella virus infection so closely as to merit diagnostic differentiation, particularly in pregnant women. Congenital abnormalities following maternal enterovirus infection have only rarely been reported.

Acute epidemic hemorrhagic conjunctivitis In 1970 there was a large epidemic of acute epidemic hemorrhagic conjunctivitis (AHC) in Singapore with more than 60 000 reported cases. The causal agent was identified as a variant of coxsackie virus A24. After an incubation period of 18–48 hours, mild to severe conjunctivitis developed, with subconjunctival hemorrhage in a minority of cases; recovery was usually complete within 1–2 weeks. Epidemics of AHC recurred in southeast Asia in 1975 and again in 1985 and in the Americas.

Enterovirus 70 first emerged in an epidemic of AHC in Ghana in 1969, spread through the coastal areas of Africa, eventually reaching India, southeast Asia, and Japan by 1970, ultimately involving hundreds of millions of people. Serological surveys in Ghana, Indonesia, and Japan confirmed that the virus was not prevalent before the pandemic. The illness had a short incubation period (24 hours), acute subconjunctival hemorrhage being the most characteristic sign; corneal involvement was usually transient and the prognosis good. The first outbreak in the western hemisphere was in Brazil in 1981 from where it then spread north, reaching Florida.

Rare cases of neurological complications accompanying or following enterovirus 70 conjunctivitis have been reported.

Respiratory disease

Respiratory illness caused by enteroviruses cannot be distinguished clinically from that caused by viruses such as rhinoviruses, parainfluenza viruses, respiratory syncytial virus, and adenoviruses. However, these viruses predominate in the winter months, whereas respiratory infection by enteroviruses typically occurs during the summer and autumn.

Diabetes

A possible association of insulin-dependent diabetes mellitus (IDDM) with coxsackie virus B infection was first suggested by Gamble in 1969. Reviews by Gamble (1980); Barrett-Connor (1985) and Toniolo et al. (1988) provide comprehensive interpretations of the available data.

A long euglycogenic period, characterized by the presence of islet cell antibodies (ICA) and T-lymphocyte responses, precedes the appearance of hyperglycemia following the near total disappearance of the β cells of the islets of Langerhans. There is some correlation of HLA haplotype (DR3 mainly in males, DR4 mainly in females) with this illness, suggesting that an autoimmune process is responsible for the chronic and irreversible loss of β cells. What triggers pancreatic autoimmunity in individuals is unknown.

Strains of coxsackie virus B4 and coxsackie virus B5 shown to be diabetogenic in mice have been isolated from people developing diabetes (Toniolo et al. 1988). It has now been shown that most of the group B coxsackie viruses are potentially able to infect and damage pancreatic endocrine cells, causing hyperglycemia. Serological studies have demonstrated that about one-third of the cases of IDDM in children are probably preceded by coxsackie virus B infection, although this may be a precipitating rather than causative factor.

Gastroenteritis

Although enteroviruses readily replicate within the gut, they are seldom the cause of gastroenteritis when this is the predominant feature.

Hepatitis

Hepatitis can accompany generalized coxsackie virus B and echovirus infections in neonates or occasionally in older children as well as following infection with hepatitis A virus (Hepatitis A and E).

Rhinoviruses

Rhinoviruses are the major cause of common colds. In the US National Health Interview Survey for 1985, colds were associated with 161 million days of restricted activity and accounted for 26 million days of school absenteeism, 23 million days lost from work and 27 million visits to physicians. More than 800 oral cold remedies are available and the annual expenditure on such treatments exceeds $2 billion in the USA.

CLINICAL MANIFESTATIONS

About 30 percent of human volunteers inoculated intranasally with nasal secretions or tissue culture fluid containing rhinoviruses develop colds, whereas less than 5 percent of volunteers given uninfected material have symptoms (Tyrrell 1965). When virus is given to adults without antibody, up to 100 percent develop colds (D'Allessio et al. 1976). At least 15 different serotypes have been given to volunteers, with essentially the same results.

In studies of university students (Gwaltney and Jordan 1966; Hamre et al. 1966; Phillips et al. 1968), industrial workers (Hamparian et al. 1964; Gwaltney et al. 1966), military personnel (Bloom et al. 1963), and civilian families (Elveback et al. 1966; Higgins et al. 1966; Hendley et al. 1969; Monto and Cavallaro 1972; Fox et al. 1975, 1985), rhinoviruses were isolated from 7–40 percent of people (including children) with upper respiratory illness but from less than 2 percent of healthy people. These findings probably underestimate the importance of rhinoviruses, because virus can be isolated from only half of known infections. The same epidemiologic studies also indicate that between 10 percent and 40 percent of rhinovirus infections are subclinical, with substantial differences in pathogenicity between serotypes.

Rhinovirus infections are more common and severe in young children than in adults (Fox et al. 1975). Rhinoviruses are also associated with lower respiratory disease in children or those with a history of chronic respiratory disease. However, in controlled studies, rhinoviruses were found in 3–8 percent of children in hospital either with lower respiratory illness or without respiratory symptoms (Chanock and Parrott 1965; Holzel et al. 1965; Stott and Walker 1967; Mufson et al. 1970). Hence, the precise role of rhinoviruses in acute respiratory disease of children is unclear (Cherry 1973). In children with a history of wheezy bronchitis or asthma, rhinoviruses are associated with up to 33 percent of acute attacks, and virus was found more often in sputum than in the nose or throat, suggesting that virus multiplies in the lower respiratory tract (Horn et al. 1979).

Rhinoviruses can cause lower respiratory tract illness in adult volunteers infected with virus in a fine particle aerosol (Cate et al. 1965). Transient abnormal pulmonary function has also been found in a small proportion of healthy volunteers after intranasal instillation of rhinovirus and in a minority of natural infections. Although rhinoviruses have been isolated postmortem from the lungs of adults who died of pneumonia, they are not implicated as a significant cause of adult pneumonia. However, in people with chronic bronchitis, rhinovirus infections have been associated with 12–43 percent of exacerbations and virus frequently seems to invade the lower respiratory tract (Stott et al. 1968). Although Buscho and colleagues (1978) found that rhinoviruses could infect patients without exacerbating their chronic bronchitis, such patients are more susceptible to rhinovirus infection than are otherwise healthy people. Furthermore, Horn and Gregg (1973) found lower respiratory tract signs in 85–90 percent of rhinovirus infections in adults with a previous history of asthma or bronchitis but in only 5 percent of such infections in otherwise healthy adults.

Bovine rhinovirus types 1 and 3 have been isolated from cattle with respiratory disease but there is little evidence to show that they are clinically important (Stott et al. 1980; Yamashita et al. 1985). There is one reported isolation of bovine type 2 virus (Reed et al. 1971). Similarly, although infection with equine rhinoviruses is widespread in horses, their precise contribution to the problem of respiratory disease is not yet clear (Powell et al. 1978).

PATHOGENESIS

Hand contact rather than aerosol is the prime mode of transmission of rhinoviruses (Gwaltney et al. 1978). Virus has not been recovered from air in rooms occupied by infected people and it is not possible to transmit rhinovirus colds between volunteers separated by a double wire mesh allowing free flow of air but no direct contact. Under the same conditions, coxsackie virus A21 was readily transmitted. Aerosols produced by talking, coughing, and sneezing derive primarily from the saliva, which has a low titer of virus, and not from the nasal secretions in which titers are highest.

By contrast, rhinovirus can readily be isolated from the hands of people during the acute stage of a cold. Furthermore, the hand contacts the eye or nose, on average, once every 3 hours. Thus, in a comparison of routes of rhinovirus transmission, 11 or 15 hand-contact exposures initiated infection but only 1 of 22 aerosol exposures was successful. Epidemiologic findings indicate that colds spread poorly in workplaces where many people share the same air space but direct contact is minimal. By contrast, transmission occurs readily within families where direct contact is frequent.

Rhinoviruses replicate in and destroy the ciliated epithelium of both nasal and tracheal mucosae, but grow to highest titer in nasal epithelium (Hoorn and Tyrrell

1965). Ciliated cells are extruded from the epithelium, leaving a generally smooth surface (Reed and Boyde 1972). Mycoplasma replication is enhanced in such virus-damaged tissue (Reed 1972), which is also probably more susceptible to secondary invasion by bacteria and mycoplasmas. Although the target cell in the lower respiratory tract is not known, type II pneumocytes may be infected by rhinoviruses in vitro (Tyrrell et al. 1979). Rhinoviruses are rarely found outside the respiratory tract, partly because their growth is restricted by temperatures above 37°C.

Host responses to infection may cause the vascular engorgement, increased vascular permeability with transudation of serum proteins and increased mucus production that are characteristic of colds. Host responses include release of inflammatory mediators, such as kinins; influxes of inflammatory cells, including polymorphonuclear leukocytes; interferon; and probably neuroreflexes and associated cholinergic stimulation and neuropeptide release (Naclerio et al. 1988). Further evidence for the role of kinins is provided by the finding that intranasal instillation of bradykinin causes some of the symptoms and alterations in nasal mucus seen in rhinovirus colds.

IMMUNE RESPONSES

Rhinovirus infection stimulates an antibody response in 47–77 percent of cases (Fox et al. 1975). The response is greater in adults than in children. Severe lower respiratory infection induces higher antibody titers than mild upper respiratory infection. Furthermore, certain serotypes are more effective antigens than others. Specific antibody in the circulation is related to protection against reinfection of volunteers. In families in which exposure to known serotypes occurred, pre-existing serum antibody was 52–69 percent effective in preventing infection. Rhinovirus infections also stimulate local IgA production. Whether secretory IgA in the mucus of the upper respiratory tract or circulating antibody in the serum is the more important in protection remains contentious (Perkins et al. 1969; Douglas and Couch 1972).

Foot-and-mouth disease

Foot-and-mouth disease is a highly infectious disease of ungulates. There are a few reports of infection in humans and experimental infections of laboratory animals are readily initiated. Seven serotypes of FMDV are recognized – O, A, C, SAT1, SAT2, SAT3, and Asia 1 – and existing vaccines are based on inactivated preparations of the appropriate serotype.

The first signs of disease in cattle are dullness, anorexia, and rising temperature, followed by nasal discharge and the appearance of vesicles in the mouth and on the feet. Initially, the vesicles in the mouth are present on the tongue, hard palate and dental pad, lips and muzzle, and on the feet in the interdigital space or along the coronary band, giving rise to lameness. The incubation period varies from 1 to 14 days.

The main routes of infection are inhalation, ingestion, or penetration of the epithelium. Virus may persist in the pharyngeal area for prolonged periods.

EPIDEMIOLOGY

Epidemiology is discussed in two sections: enteroviruses and rhinoviruses.

Enteroviruses

MODE OF TRANSMISSION

Humans are the only known reservoir for members of the human enterovirus group. Virus is generally shed for longer periods in feces (1 month or more) than from the oropharynx, and fecal contamination is the usual source of infection although enterovirus 70, the agent of acute hemorrhagic conjunctivitis, has been found almost exclusively in conjunctival and throat specimens.

INFLUENCE OF CLIMATE

In temperate climates enteroviruses are more prevalent in the summer and autumn (i.e. when warmth and humidity are at their peak). In tropical climates they tend to circulate all the year round or are associated with the rainy season.

SPREAD WITHIN FAMILIES

Young children are the usual reservoir of enterovirus infection. The secondary attack rates in susceptible family members are reported as 92 percent for polioviruses, 76 percent for coxsackie viruses and 43 percent for echoviruses. The greater spread of polioviruses and coxsackie viruses may be related to their longer periods of excretion. Secondary coxsackie virus infections were more common in mothers (78 percent) than in fathers (47 percent). Coxsackie viruses spread to 75 percent of exposed susceptibles but to only 25 percent of exposed people who already had antibody to the infecting type; echoviruses infected 43 percent of susceptibles and only one person with homotypic antibody.

EPIDEMIOLOGICAL SURVEILLANCE

International data

In 1963 the World Health Organization established a system for the collection and dissemination of information on viral infections. Although the level of reporting may be low and variable, the data are of interest in identifying viruses implicated in clinical syndromes. Examples from 1975 to 1983 are shown in Tables 5 and 6.

The commonest coxsackie virus reported was coxsackie virus A9, the serotype most readily detectable in

cell cultures. Coxsackie virus A16 is the main cause of HFMD. Over all, coxsackie virus B4 was the serotype associated with the widest range of syndromes; coxsackie virus B5 was the predominant serotype linked with nonparalytic CNS infections and rashes.

Almost half the reported echovirus infections were associated with CNS disease, especially aseptic meningitis (Table 6). Echoviruses 6, 9, 11, 19, and 30 are regularly encountered during outbreaks of aseptic meningitis, sometimes accompanied by a rash in echovirus 6 and 9 infections. Parechovirus 1, echovirus 22 is usually associated with a 'failure to thrive' syndrome in infants less than 1 year old and is seldom associated with CNS infection. The apparent role of coxsackie viruses A and B and, to a lesser extent, the echoviruses in paralytic disease should be interpreted with caution because most reports are based on virus isolation from feces alone.

Infections due to enterovirus serotypes 68–71 reported to WHO during 1975–83 and the associated illnesses are listed in Table 7.

Illness due to enteroviruses 68 and 69 is uncommon. Although the figures clearly show the association of enterovirus 70 with eye infections, they fail to reveal the pandemic nature of this virus in acute hemorrhagic conjunctivitis; enterovirus 70 is difficult to isolate in cell culture and this alone might explain the discrepancy. Enterovirus 71 is more readily isolated from clinical specimens, and its associations with CNS infections and HFMD (or both concurrently) are apparent from Table 7.

Peak virus activity was seen in July in the northern hemisphere, and during December to January in the southern hemisphere.

As shown in Table 8, enterovirus infections were more common in children, especially in those aged 1–4 years.

Rhinoviruses

Rhinovirus infections are seen throughout the year but are most prevalent in the spring and autumn when sudden changes in temperature are common. It has been suggested that rapid temperature changes are closely associated with the incidence of colds (Hope-Simpson 1958). Rhinoviruses are distributed throughout the world, and antibodies to them have been detected even in the remote communities of Alaskan Eskimos, Pacific Micronesians, and Kalahari Hottentots.

The multiplicity of rhinovirus serotypes is a major factor in their epidemiology. Several serotypes circulate simultaneously within a community, and an individual may be infected with two serotypes at the same time (Cooney and Kenny 1977). Some serotypes persist continuously in a population for several years whereas others may appear transiently. The distribution of sero-

types has changed over the years. Before 1967 most isolates belonged to the first 55 serotypes; in 1968 and 1969 fewer than half the isolates were serotypes 1–55 and an increasing number were types 56–89. Between 1970 and 1975, 50 percent of rhinoviruses isolated did not belong to the first 89 types (Fox 1976). However, more recent publications indicate that over 90 percent of rhinoviruses isolated can now be identified as known serotypes (Fox et al. 1985; Hamparian et al. 1987). Some serotypes, such as 1B, 12, 15 and 38, are isolated more often than others, possibly because they spread more effectively. Certainly, the more frequently isolated serotypes cause a higher secondary attack rate in family surveys (Fox et al. 1975). However, it must be remembered that frequency of isolation may just reflect the sensitivity of the cell cultures used rather than the distribution of viruses in a population.

LABORATORY DIAGNOSIS

Enteroviruses

Detailed descriptions of the principles and procedures for the diagnosis of enterovirus infections are published elsewhere (Grist et al. 1979).

COLLECTION OF SPECIMENS

The usual specimens for virus isolation are feces (or rectal swabs) and throat swabs. **Fecal** excretion of virus commences within a few days of infection and may continue for weeks in children with poliovirus and coxsackie virus infections, although it rarely exceeds 1 month with the echoviruses; in adults it is usually of shorter duration (1–2 weeks). Excretion in the feces is often intermittent, so, ideally, more than one sample should be collected at least 1–2 days apart. Isolation of virus from pharyngeal secretions is possible up to 1 week after onset of symptoms. Culture of virus from the CSF is an essential part of the routine laboratory diagnosis of patients with aseptic meningitis.

VIRUS ISOLATION IN CELL CULTURES

Polioviruses, the coxsackie B group viruses, and the echoviruses have been readily isolated in kidney cell cultures prepared from rhesus or cynomolgus monkeys or baboons which may not be readily available nowadays. Other susceptible cultures can be obtained from human amnion, diploid cells of human embryo lung, and the RD cell line derived from a human rhabdomyosarcoma. Polioviruses can be isolated in HEp-2c cells or the L20B line (Pipkin et al. 1993).

IDENTIFICATION OF SEROTYPES

Serotypes may be identified by reference antisera. These LBM pools (devised by Lim, Benyesh, and Melnick) are issued in freeze-dried form to reference centers after formal requests to WHO, Geneva. There are eight pools of antisera (A–H) against 42 enteroviruses that grow readily in cell culture and a further seven pools (J–P) of antisera against 19 coxsackie virus A serotypes that grow readily only in newborn mice (Table 9) (Melnick and Wimberly 1985).

ANTIGENIC VARIATION

Antigenic variation in the enteroviruses can give rise to prime strains that may not be neutralized by sera to the prototype strain, but can induce antibodies that neutralize the homologous and prototype strains equally well. Intratypic variants have also been described for coxsackie viruses A24, B1–4, B6, echoviruses 4, 9, and

Table 8 *Global surveillance of enteroviral infections by age, 1975–83*

F	None	B6	E7, 9, 14, 18–20, 26, 27, 29	P1
G	A9	B3	E4, 5, 16, 17, 20, 23, 30, 31	None
H	A16	B6	E1, 3, 9, 12, 22, 23, 32	P3

Antisera against 19 additional coxsackie A viruses are contained in pools J–P. Data from Melnick and Wimberly (1985).

33 and enterovirus 70. Unlike prime strains, intratypic variants have a narrower antigenic spectrum than their corresponding prototype strains.

Aggregation of virions may also cause problems in the neutralization test. The Pesascek strain of echovirus 4 is poorly neutralized by homologous antisera, whereas the Du Toit strain is readily neutralizable. Virus in non-neutralizable aggregates was found to constitute up to 30 percent of untreated Pesascek stock virus preparations but only 0.1 percent of Du Toit stocks. Methods used to disaggregate enteroviruses include filtration or treatment with chloroform.

VIRUS ISOLATION IN NEWBORN MICE

Coxsackie virus A is not readily detected in cell cultures (Table 10). Isolation requires that specimens should be injected into litters of newborn mice (24–48 hours old) by intracerebral, intraperitoneal, and subcutaneous routes. The group A viruses induce general myositis of striated muscle, causing flaccid paralysis and death. The B group cause spastic paralysis and degenerative changes in the brain and necrosis of the brown fat.

TEST FOR ANTIBODIES

A few diseases – notably pleurodynia, HFMD, and acute hemorrhagic conjunctivitis – are so regularly associated with particular serotypes (viz. coxsackie viruses B1–5, coxsackie virus A16, and enterovirus 70, respectively) that their serological diagnosis is often feasible; in other situations virus isolation is the best approach. Antibody titers are compared in paired sera, the first sample being collected in the acute phase and the second 1–14 days later. Enzyme-linked immunosorbent assay (ELISA) or radioimmunoassay may be used as well as neutralization or, in some cases, hemagglutination inhibitor. Such methods can be used to assay for IgM specifically, and thus identify acute infections.

MOLECULAR BIOLOGICAL METHODS

Polymerase chain reaction (PCR) is increasingly applied to clinical specimens and isolates, particularly using primers able to amplify a wide range of enterovirus sequences, which can then be studied further. The use of PCR obviates the need for specific sera if regions of the genome encoding structural proteins are amplified (see above under Classification). Isolation may also be unnecessary, and this may change the spectrum of enteroviruses detected, specifically where they are difficult to grow in culture as for the coxsackie A viruses. Viral sequences have been commonly reported from samples of CSF and serum which is usually a poor source for virus isolation. The advantage of isolation is that it provides permanent specimens for later study. It is likely to become less common except in specialized centers in the future.

Rhinoviruses

Rhinovirus infections are normally diagnosed by isolation of virus from respiratory secretions. As for the

Table 10 *Comparative sensitivity of enterovirus isolation systems*

Virus group	Primary monkey[a]/ baboon	Primary human amnion	Human embryo lung (semi-continuous)	RD[b]	Newborn mice

c) Coxsackie virus A7, A9, A10, A16.
d) Coxsackie virus A21: −, nil; ±, poor; +, good; ++, very good.

enteroviruses, serological techniques have only limited value because of the large number of serotypes and the absence of a specific rhinovirus group antigen.

Rhinoviruses are most often isolated from nasal washings but throat or nasal swabs and sputa are suitable alternative samples. Virus is rarely isolated from blood.

Specimens should be transported to the laboratory in a buffered medium containing about 1 mg of protein (e.g. bovine plasma albumin) per milliliter and inoculated into cell cultures as soon as possible. Most rhinoviruses are strictly species-specific. Therefore, apart from the few strains that grow in monkey kidney cells, human rhinoviruses will grow only in cells of human origin. Semicontinuous cell strains from human embryonic lung are the most widely used for virus isolation, although certain virus strains are isolated more readily in diploid cells from human embryonic kidney or tonsils. Semicontinuous cell strains from different human embryos vary considerably in their sensitivity to rhinoviruses and these differences are not always revealed by titration of laboratory passaged viruses (Stott and Walker 1967; Fox et al. 1975). A continuous line of HeLa cells, sensitive to rhinoviruses, may also be used for primary isolation (Cooney and Kenny 1977). Bovine rhinoviruses are usually isolated in secondary calf kidney cells. All cell cultures inoculated with rhinoviruses should be rolled at 33°C in medium with pH below 7.6. Virus-infected cultures develop small areas of refractile cells, usually within 7 days. Such cytopathic agents are tentatively identified as rhinoviruses by demonstrating that they resist chloroform or ether, pass through a 50 nm filter, grow in the presence of bromodeoxyuridine (a DNA inhibitor) and are destroyed at pH 5. Final identification of a rhinovirus serotype requires neutralization by specific antiserum but this procedure can be simplified by combining antisera into a scheme of pools (Kenny et al. 1970).

Organ cultures of human embryonic trachea or nasal epithelium support the growth of some rhinoviruses that cannot be isolated in cell cultures. Although most of these viruses can subsequently be passaged in cell culture, some apparently replicate only in organ cultures.

When the infecting serotype is known, as in volunteer trials, virus antigen can be detected in nasal washings by ELISA, using specific polyclonal or monoclonal antibodies.

Molecular methods can also be applied. Deoxyoligonucleotides complementary to conserved sequence of the 5′ noncoding region hybridize to the RNAs of all 57 rhinovirus serotypes so far tested and also detect virus in nasal washings specifically and efficiently (Bruce et al. 1988). This approach has the further advantage that cDNA to this region of viral RNA may be specifically amplified by PCR, increasing the sensitivity of the technique.

Serological diagnosis of rhinovirus infection by demonstrating rising antibody titers is practicable only when the serotype of the infecting virus is known. The microneutralization test has been widely used for the detection of rhinovirus antibodies. The hemagglutination inhibition test is particularly useful for the rapid screening of volunteers for antibodies before inoculation (Reed and Hall 1973) but can, of course, be used only for serotypes that hemagglutinate. This restriction does not apply to ELISA or complement fixation tests.

CONTROL OF ENTEROVIRAL INFECTIONS

There are no established antiviral agents for the prevention or treatment of enteroviral diseases although a number of experimental drugs have been used in clinical trials. Pleconaril, an agent which inserts into the viral capsid and prevents the virus binding to the cell and subsequently uncoating, has been used in trials to attempt to interrupt chronic enterovirus infections of hypogammaglobulinemic patients. Quarantine of patients, or contacts, is of little use because most infections are inapparent and spread among close contacts is rapid. A degree of control can be achieved in special baby-care units (where enterovirus infections can often prove fatal), by 'barrier nursing,' an increase in general hygiene of the staff, and exclusion of staff and parents with even 'minor' illnesses. Similar precautions in eye clinics may help when acute hemorrhagic conjunctivitis is present in the community.

Use of immunoglobulin

Commercially prepared γ-globulin may be useful in preventing enteroviral disease, especially in nurseries threatened by serious outbreaks of group B coxsackie viruses. Its use halted an outbreak of echovirus 11 in a premature baby unit in England in 1983.

Prophylaxis: rhinoviruses

The use of formalin-inactivated rhinovirus 1A vaccine to induce antibody was first described in 1963 (Doggett et al. 1963; Mufson et al. 1963). Subsequently, similar inactivated vaccines made from rhinoviruses 2 and 13 have been administered by subcutaneous, intramuscular, or intranasal routes and have protected volunteers against live virus challenge. The problem of numerous serotypes with little or no cross-protection remains.

SPECIFIC THERAPY

In a review of chemotherapy for rhinovirus infections, Sperber and Hayden (1988) have pointed out that treatment may be aimed at either the virus or the symptoms it induces.

Many compounds specifically inhibit rhinoviruses in vivo but few have beneficial effects against infection in vivo, although some are used in symptom relief. Interferon, zinc salts, synthetic antiviral agents, and monoclonal antibodies have been tested against rhinovirus colds in placebo-controlled trials.

Natural and recombinant human interferons have been tested clinically. Recombinant interferon-α2, administered intranasally, protects against natural and experimental rhinovirus infections. However, no therapeutic benefit is observed even if treatment is started within 30 hours of virus challenge.

A number of compounds are now available that specifically bind to rhinovirus capsids and block uncoating. The Sterling–Winthrop compound disoxaril and its derivatives have powerful antiviral effects both in vitro and in animals inhibiting viral uncoating. It has been established by X-ray crystallography that this drug acts within the VP1 β barrel of the capsid. Two other compounds, dichloroflavan and R61837, also inhibit rhinovirus uncoating, and probably bind to a similar region of the capsid. In clinical trials, dichloroflavan was ineffective but R61837 had significant benefit when given intranasally before an experimental rhinovirus challenge. Enviroxime, a benzimidazole derivative, seems to inhibit the formation of the viral RNA polymerase replication complex. When given orally and intranasally before the challenge, enviroxime significantly reduced production of nasal mucus. However, no therapeutic benefit has yet been demonstrated.

Murine monoclonal antibodies directed against the major group cell receptor compete with rhinoviruses in vitro and displace previously bound virions from cells, thus inhibiting infection. One of these monoclonal antibodies, administered intransally and prophylactically to humans, modified experimental rhinovirus infection both clinically and virologically.

A major pharmacokinetic obstacle to effective therapy is the maintenance of an adequate concentration of drug in respiratory mucosae where rhinoviruses replicate. Furthermore, successful therapies must work rapidly and be free of any side effects.

Prophylaxis: the eradication of poliomyelitis

Polioviruses are believed to have been established throughout most of the population of the world from ancient times, surviving in an endemic form by infection of susceptible infants. Because of the universal presence of antibody to all three serotypes in women of childbearing age, and the protective effect of maternal antibody on disease but not gut infection, most infants would be infected while still protected. Improvements in standards of hygiene in the late nineteenth century led to a delay in the exposure of infants to an age when maternal antibody had declined to non-protective levels. Patterns of disease then changed from the relatively uncommon and endemic kind to the occurrence of large epidemics, and poliomyelitis also became known as infantile paralysis. Safe and effective polio vaccines were developed and used in the 1950s and had an immediate and impressive effect in developed countries. The incidence of poliomyelitis in the USA between 1951 and 1979 is shown in Figure 40.7.

INACTIVATED POLIO VACCINE

The first of the currently used vaccines to be developed was the formalin-inactivated preparation of Salk (1960). Virus was treated with low concentrations of formalin under carefully controlled conditions to ensure that infectivity but not immunogenicity was lost. The resulting inactivated polio vaccine (IPV) is administered

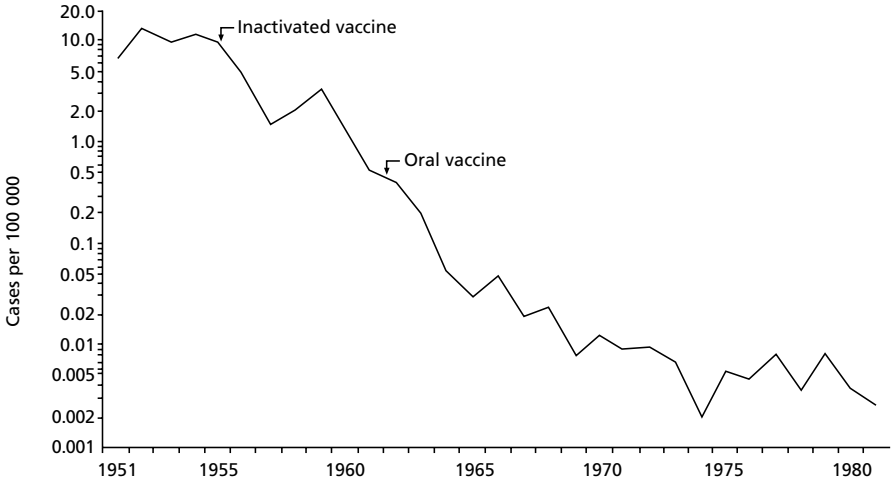

Figure 40.7 *Incidence of paralytic poliomyelitis in USA from 1951 to 1979, showing the effect of vaccination*

by injection; in the early days there were significant problems of production, particularly of the type 1 component which is the least immunogenic of the serotypes in IPV. Immediately after the licensure of the vaccine, batches were used that contained imperfectly inactivated virus, resulting in paralysis in recipients. This was the Cutter incident (Nathanson and Langmuir 1963), and is attributed to the presence of aggregates in which the virus at the center of a clump was protected from inactivation. Production was revised at once to introduce filter steps before and after treatment to remove aggregates, and no case of poliomyelitis attributable to IPV has been reported since. However, filtration removed viral antigen, making the supply problems more intense, and it was not until the 1980s with the development of improved high-density cell culture systems that high-potency IPV [enhanced potency IPV (EIPV)] became available. Its use in developed countries is increasing at the expense of the live attenuated vaccine.

LIVE POLIO VACCINE

The relative merits of inactivated polio vaccine and live attenuated vaccines were and remain a matter of heated debate. Both are highly effective and safe, but it is argued that the live, oral polio vaccine OPV developed by Sabin (Sabin and Boulger 1973), which imitates natural gut infection, also stimulates gut immunity effectively, preventing reinfection and thus interrupting transmission. Whilst it can be shown that even recent OPV vaccinees can be reinfected by wild-type strains, OPV is effective in breaking transmission in epidemics. This may be due to gut immunity or to simple competition. OPV is known to spread from person to person to some extent, which can be an advantage if not all susceptible individuals are immunized directly. Where countries have used IPV alone, unimmunized subpopulations can suffer outbreaks. For example, a religious group in Holland experienced outbreaks of type 1 in 1976 and type 3 in 1993.

The Sabin vaccine strains were developed by passage in vivo or in vitro and selected for reduced neurotropism by tests in primates. The molecular basis of this attenuation for primates was studied intensively in the 1980s and 1990s (Minor 1992).

The type 3 strain was studied in particular because it failed the primate safety test more often than types 1 and 2. Complete sequences of the genomes of the virulent precursor strain (Leon), the vaccine strain (Leon 12_{a1b}), and a virulent revertant isolated from a fatal case of vaccine-associated poliomyelitis were determined and compared to identify features common to the virulent strains that distinguished them from the vaccine strain. Recombinant viruses were made in which portions of the attenuated vaccine strain genome were exchanged for the equivalent region of the Leon genome to identify changes that would attenuate. Finally, a deattenuated version of the Sabin type 3 vaccine strain was made in which all bases thought to have an attenuating effect were reverted to the virulent form. The conclusion from these studies was that only two mutations were responsible for the great majority of the attenuation of the Sabin type 3 vaccine strain. They were a base change at residue 472 in the 5′ noncoding region, and a coding change leading to a substitution of a phenylalanine residue for a serine residue at position 91 of the capsid protein VP3. The 5′ noncoding change leads to a loss of efficiency in the initiation of protein synthesis in in vitro translation systems (Svitkin et al. 1985), and the change in VP3 affects capsid assembly and is responsible in large part for the fact that growth of the Sabin vaccine strain is greatly inhibited at high temperatures. Other changes may make some contribution to the attenuated phenotype, but these two cause the only effects readily detectable in the standard virulence tests.

Comparable recombinants were made between the type 1 Sabin and the virulent type 1 Mahoney strains. The relatively large number of differences between the strains made detailed analysis more difficult, but it was concluded that a major attenuating mutation was to be found at base 480 in the 5′ noncoding region, comparable to that found in type 3, and that other mutations were scattered through the genome, most if not all in the structural proteins. For type 2, there is evidence for a mutation in a similar location in the 5′ noncoding region at residue 481, and in structural protein VP1 at residue 143. There is evidence from examination of the rare cases of vaccine-associated poliomyelitis that occur that the mutations identified in the animal model systems also attenuate the vaccine for humans.

THE ERADICATION OF WILD POLIOMYELITIS

In 1988 the World Health Organization declared the goal of eradicating all wild-type poliovirus and thus the cases of poliomyelitis that they caused by the year 2000. While this target date has passed, there is every possibility that the goal will be achieved in the near future. The reader is referred to the website for current information (www.polioeradication.org). Both live and killed vaccines have been shown to be highly effective but the live attenuated vaccine has been the most widely used because of ease of administration and cost; it is also proven to be able to interrupt epidemics of disease, although initially it was widely considered that it was not effective in developing countries. Various reasons were given to explain this, including possible interference with vaccine take by intercurrent intestinal infections, but the main reasons are probably twofold. First, the infrastructure in tropical countries is usually less well developed than in the temperate climates where the vaccine was shown to work, so that the quality of the vaccine could be very poor by the time it was used. Second,

infection with poliovirus in temperate climates is markedly seasonal, with transmissions occurring only in the warmer summer months. Thus, when following the usual practice of immunizing children at a set age, the pool of susceptible individuals could be reduced greatly during the winter, when no virus transmission occurred, so that transmission was more difficult in the summer when the virus returned. By contrast, in tropical climates infection is year round, although there may be an element of seasonality. It is therefore a matter of chance whether an individual encounters the vaccine or the wild-type virus first, and there is no period of respite when immunization can make sufficient inroads on the susceptible population to affect person-to-person spread.

The solution to the problems was first to develop systems (cold chains) by which the quality of vaccines could be maintained by keeping them cold from the point of manufacture to the point of use. Second, the vaccine was used in a way that mimics an epidemic, namely by immunizing very large numbers of susceptibles within a very short period. This has taken the form of National Immunization Days (NID), which may involve the vaccination of 120 million children in a single country in a single day. As all susceptible intestines are occupied by vaccine, or are immune because of the vaccine, transmission of the wild-type virus is interrupted and in practice the wild-type virus can be eradicated in a particular limited region by a few well-conducted NIDs. Problems of access to regions of conflict or areas of particularly poor infrastructure arise, but the effect of the strategy has been to reduce the number of countries in which the virus is endemic to ten or less as of late 2002, with most concern arising from India and Nigeria. The Americas were certified free of polio in 1991, the Western Pacific Region of WHO including China in 1994, and the European Region in 2002. Even areas such as the Democratic Republic of Congo where savage wars are in progress and numbers of vaccine workers have been killed in the course of immunization programs are credibly free of poliomyelitis caused by the wild-type virus. Whilst wild-type poliovirus is still present in a few parts of the world, and in 2002 there were setbacks in both India and Africa in terms of numbers of cases identified, it is likely that the last wild-type 2 virus in the world was isolated in 1999, and that sooner rather than later the other two serotypes will also be eliminated.

One of the important factors in monitoring the progress of this exercise was the demonstration that virus transmission in a particular region had been interrupted. This depended on the specific identification of virus strains, accomplished by sequencing a relatively small part of the genome encoding the region around the *VP1-2A* gene (Rico-Hesse et al. 1987) or the region encoding the whole of VP1. Such sequences can be used to construct dendrograms of relatedness, and it has been possible to identify 'genotypes' of the different serotypes, defined as strains differing by 15 percent or less in sequence. The genotypes were found to be geographically clustered; thus an isolate from the Middle East would closely resemble other isolates from the Middle East, including those made some time ago. It was therefore possible to identify a particular virus as indigenous to the country of origin or imported, and if so, from where. For example, in 1984 a small outbreak of type 3 poliomyelitis occurred in Finland in which there were nine paralytic cases and one case of aseptic meningitis. Circulation of the strain was widespread despite the use of IPV in Finland, and there was some evidence that the strain was antigenically unusual. Genomic analysis revealed that the strain originated from the Middle East, possibly imported by soldiers serving with the UN.

CESSATION OF VACCINATION

One of the anticipated benefits of eradication is the cessation of vaccination, with consequent savings. It is also likely to be difficult and possibly unethical to maintain vaccination programs after the disease is eradicated. Stopping vaccinating is easier said than safely done, however. The molecular basis of the attenuation of the live vaccine strains of poliovirus developed by Sabin established in the 1980s and 1990s (Minor 1992) shows that for each of the strains there were relatively few mutations involved, two for each of the type 2 and 3 strains and a few more for the type 1 strain. In each case a mutation in the 5′ noncoding region had an effect with one or more mutations in the structural proteins and so far as can be seen there are no attenuating mutations in the nonstructural proteins.

The vaccines are extremely safe and effective but they all derive from original circulating natural isolates; the type 3 strain came from a fatal case. Moreover, it has been conclusively demonstrated that in rare instances, estimated at about one per 750 000 first-time vaccinees or one in 2 million overall, the vaccine can itself cause poliomyelitis in recipients or their contacts. In view of the small number of attenuating mutations, this is not surprising.

However, even when normal healthy vaccinees were examined it was found that the virus was capable of extraordinarily rapid and accurate adaptation and mutation (Minor et al. 1986b). For type 3, the mutation in the 5′ noncoding region, which is one of two that attenuate, the virus was lost at the latest within 6 days and usually within 3. The other mutation in the structural proteins is usually suppressed by changes at other positions rather than back mutation at about 11 days after vaccination; the suppressor mutations may affect other steps in the assembly of the virus than that affected by the attenuating mutation, and therefore compensate for its effects indirectly.

In addition, it was found that recombination between the viruses in the vaccine was extremely common. In

fact it has been found to be the rule that a child excreting type 3 poliovirus more than 11 days after vaccination will be producing a recombinant virus in which the structural proteins derive from type 3 and the nonstructural proteins from types 1 or 2. Complex recombinants of all three serotypes are common.

The fact that the vaccine strains were derived from transmissible paralytic circulating strains of virus, that they can, albeit rarely, cause paralysis in recipients and in their contacts, coupled with the rapid evolution of the virus in vaccine recipients, suggests that it should be possible to select an epidemic, transmissible paralytic strain of poliovirus from the vaccine given the right conditions. Current observations confirm this possibility and give cause for concern.

PERSISTENCE AND CIRCULATION OF VACCINE-DERIVED VIRUS

One strategy for the cessation of vaccination would be simply to stop when it was certain that wild-type virus had been eradicated. The assumption on which this is based is that the vaccine virus does not circulate readily, and that it will therefore die out before sufficient susceptible individuals accumulate to maintain it in circulation. It is possible that this strategy would be successful. In certain countries vaccine is given at one set time. In Cuba, vaccine is only given twice at the beginning of the year and virus cannot be isolated from sewage specimens 6 months later. It has been shown that on average a vaccinee excretes poliovirus for about 5 or 6 weeks, with only one percent continuing for 10 weeks. It is believed that immunocompetent individuals never excrete the virus for longer than 6 months. Moreover, early studies showed that in the population studied which was in Louisiana, USA, the virus died out after three person-to-person transmissions. Thus virus excretion in the main is of limited duration and transmission is not very effective.

However, there have been several separate incidents in which small outbreaks of poliomyelitis have occurred after the eradication of the wild-type and where the causative virus is clearly related to the vaccine strain (Figure 40.8). They include type 2 strains isolated in Egypt between 1988 and 1993, strains responsible for an outbreak on the island of Hispaniola in Haiti and the Dominican Republic, which caused more than 20 cases in 2000–01 (Kew et al. 2002), a very small outbreak in the Philippines in 2001, and in Madagascar in 2002. The strains had some features in common. It is possible to date the origin of the strain by examining the sequence of the viral genome. During epidemics, the sequence drifts at a remarkably constant rate of about 3 percent for the silent mutations that do not cause amino acid changes, or about 1 percent if all mutations are considered (Martin et al. 2000a, 2000b). The rate seems to be independent of the type or the specific outbreak, and based on this molecular clock the strains in the incidents listed above had been circulating undetected for 1–2 years. When they were examined in more detail, it was found that all were recombinant viruses between the vaccine strains and an unknown virus, which was not any of the vaccine strains. As poliovirus was either rare or eradicated in each of the countries concerned, it is assumed that the partner virus was a nonpolio group C enterovirus. As described above, the sequence data available suggest that recombination between members of this group occurs readily. In Hispaniola and in Madagascar there were several distinct recombinant viruses, indicating that multiple recombination events had taken place. The reason why all so far have been recombinants is not known, nor is there any understanding of what makes the viruses readily transmissible when the parent vaccine strain is not. The level of virus excreted is very similar in the outbreak cases and in normal vaccinees; it is tempting to speculate that the recombinant nature of the viruses plays a part, but it may be fortuitous. As stated above, all the vaccine strains originated from circulating strains of some sort and in principle it should be possible for them to regain transmissibility, particularly in the light of the rapid adaptation of the viruses in vaccine recipients. The origin of the strains is also speculative, but plausible. When poliomyelitis is eradicated from a region, the motivation for continuing vaccination dwindles and other health issues get attention. In Haiti, vaccine uptake was about 50 percent; in the other regions it was higher, typically about 80 percent overall. Thus while some of the susceptible children were given live vaccine, which they excreted, others were not, a situation that persisted for several years. This scenario is ideal for the selection of transmissible viruses and it seems almost inevitable that they would arise wherever vaccine programs gradually fade away. The solution could be to immunize the population to high coverage and then stop vaccinating altogether. This would at least reduce the time available for selecting transmissible strains.

CHRONIC EXCRETION OF POLIOVIRUS

A second hazard to the cessation of vaccination arises from the existence of hypogammaglobulinemic patients who may excrete virus for very long periods. So far as is known, such patients are relatively rare; at the time of writing the total number is fewer than 20. Moreover, there is no documented case of any of them acting as a source of infection for others. Some excrete virus for a prolonged period of 1 or 2 years and then stop spontaneously for known or unknown reasons; in one case excretion of virus stopped 3 years after a *Shigella* infection but usually there is no identifiable cause. However, there are instances where virus excretion had persisted for 10 years or more before it was detected, based on the sequence of the viruses, where the molecular clock seems to operate at the same rate as in an epidemic. Most patients have been identified because they develop poliomyelitis; exceptions include

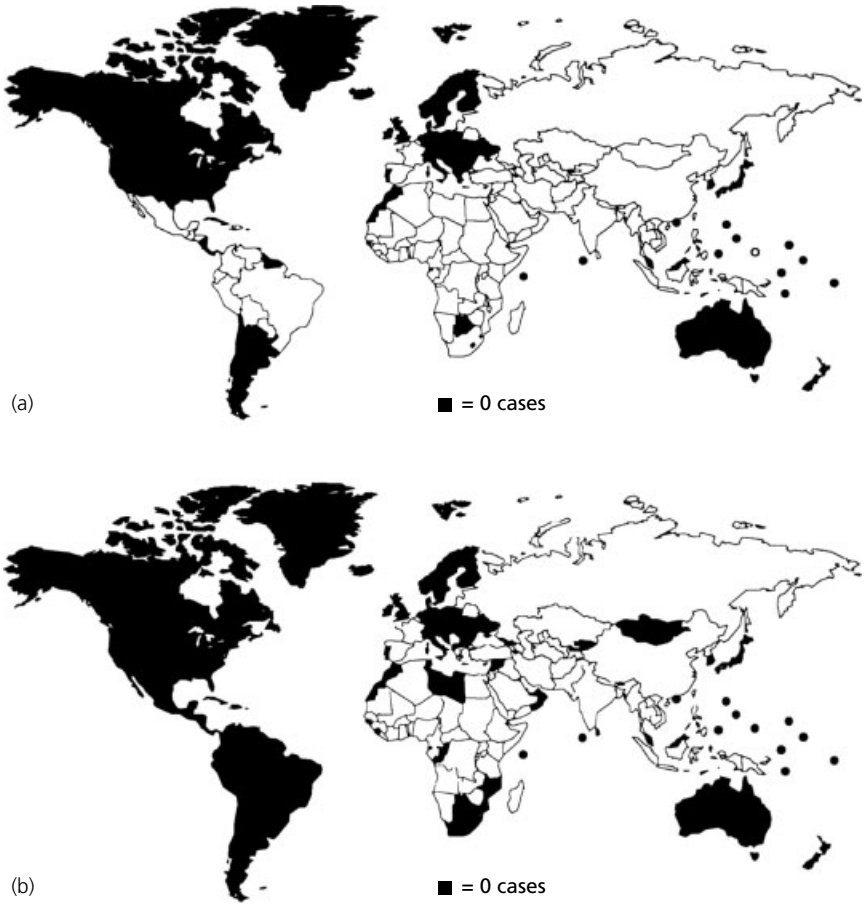

Figure 40.8 *Global distribution of poliomyelitis in* **(a)** *1988 and* **(b)** *1994. Shaded areas indicate countries with no reports of poliomyelitis due to wild-type virus.*

two patients who were deliberately given vaccine in the 1960s to investigate residual responses and protect them from wild-type poliovirus which was epidemic in the UK at the time. Some patients have been discovered by accident in the course of other investigations. Probably the best documented case is an individual who is currently known to have been excreting poliovirus in 1995 and was still doing so in 2002. Based on the sequence data, the patient is likely to have been excreting virus for 20 years. The virus is excreted at high levels in the stool and is highly virulent in animal models; it has also lost all molecular markers of attenuation. It seems likely that such individuals could act as origins of the virus in a post-eradication setting. They are rare, but nonetheless they occur. As hypogammaglobulinemia is mainly a disease of Caucasians, it may be that the hazard they pose is less by virtue of the high living standards and level of public hygiene than if they occurred in poorer parts of the world. The possible effect of AIDS has been raised; so far as is known, it does not increase the risk of long-term excretion of poliovirus, which is associated with a defect in humoral immunity. Extensive studies have not been carried out, however.

POSSIBLE SOLUTIONS

At the time of writing, the solution to the persistence of poliovirus from whatever source is not clear. Many developed countries have switched to the use of inactivated polio vaccine which at worst will maintain immunity while the significance of the issues raised can be evaluated. It has been proposed that vaccination should continue indefinitely, or that it should cease abruptly, which is likely to make the occurrence of the circulating strains found in Hispaniola and the other instances cited above less likely. New vaccines based on stabilized strains or nonreplicating vaccines have also been suggested. The possibility of bioterrorism or the escape of wild-type poliovirus from laboratory or other sources, or even the re-evolution of the virus from one of the other group C enteroviruses means that some reserve vaccine stock will be required. The form it will take and the strategies for its use remain to be established.

FUTURE PROSPECTS

Poliomyelitis due to wild-type virus is very likely to be eliminated in the near future. At that point the only way

of contracting poliomyelitis will be by vaccination, which will therefore presumably stop. The strategy for doing so has not yet been elaborated, but the risk is that the vaccine strains will occupy the niche occupied by wild poliovirus, and, in view of their ability to adapt, that they will become virulent. It will therefore be necessary to protect individuals for some time until it can be shown that the vaccine-derived strains are not circulating freely but have died out. It is likely that this will be done by changing to the use of IPV rather than OPV, accompanied by suitable environmental monitoring. In Finland after the 1984/85 outbreak, OPV was used extensively but was only detectable in sewage for a period of a few months. It is therefore possible that circulation will not be prolonged, and that poliomyelitis will become the second disease to be eliminated, after smallpox.

Astroviruses are a relatively newly classified family of nonenveloped small RNA viruses. They appear to be widespread in nature and the list of family members and their known host species is increasing steadily. Most members are enteric and are an important cause of diarrhea and vomiting in the young of both humans and animals. In common with most agents of this type, the viruses seem to be highly resilient and survive well in the environment.

Human astroviruses (HAstV) were the first to be identified and were observed during electron microscopic examination of diarrheal stools from infants (Appleton and Higgins 1975; Madeley and Cosgrove 1975a). Their distinctive and unique appearance under negative stain (Figure 1) immediately suggested a novel type of virus. The particles were rounded in shape, 28 nm in diameter with a smooth margin, and, most distinctively, approximately 10 percent of them displayed a five- or six-pointed star motif on their surface. The term 'astrovirus' (Greek: astron – star) was coined to refer to this feature (Madeley and Cosgrove 1975b). Viruses showing this characteristic appearance have since been found in the stools of a variety of mammals including cattle (Woode and Bridger 1978), sheep (Snodgrass and Gray 1977), pigs (Bridger 1980), cats (Hoshino et al. 1981; Harbour et al. 1987), dogs (Williams 1980), mink (Englund et al. 2002), and mice (Kjeldsberg and Hem 1985). All were associated with mild diarrhea, generally in the young of the species. Astroviruses have also been found to infect birds including turkeys (McNulty et al. 1980), chickens (Yamaguchi et al. 1979), and ducks (Gough et al. 1984), but in avian species the symptoms may vary. The duck

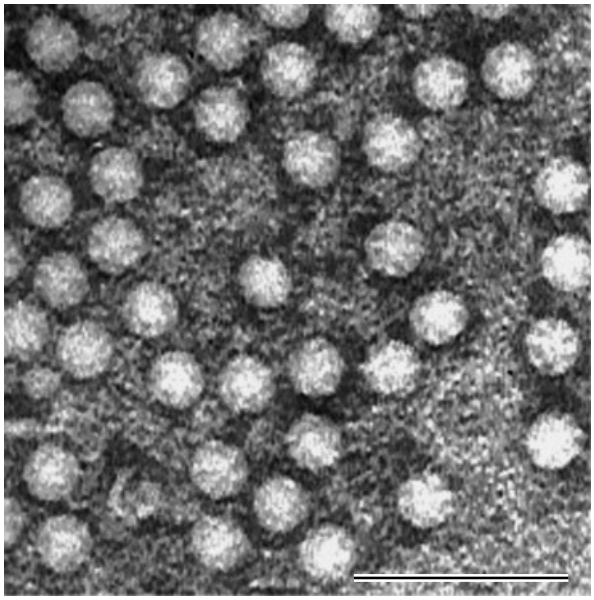

Figure 1 *Human fecal astroviruses negatively stained with phosphotungstic acid and viewed under the EM. Star-like motifs are visible on the surface of some particles, those showing both five- and six-pointed stars are visible. Bar 100 nm*

astrovirus DHV II causes a necrotic hepatitis, turkey astroviruses (TAstV) are associated with immunosuppressive disease or diarrhea, and the chicken virus causes nephritis. Astroviruses are a significant cause of mortality in all these species.

As is the case with other viruses infecting the gut, astroviruses are also observed in stools from symptom-free individuals and are also found in association with other enteric viruses. These features complicate attempts to assess the significance of astroviruses in human disease. Electron microscopy (EM)-based studies showed relatively few diarrheas were astrovirus-associated even though infection was known to be widespread. This in turn suggested that infections must usually be relatively mild or inapparent. Although this remains probable, recent evidence suggests that the 'typical' astrovirus structure described above may not have been a reliable feature for identification and studies using alternative technologies indicate a more significant virus association with symptomatic illness.

Initial attempts to culture these viruses failed and so the first investigations were carried out using ovine astrovirus (OAstV) since this could be obtained relatively easily from experimentally infected lambs (Herring et al. 1981). A major landmark in astrovirus research occurred with the adaptation of HAstV to cell culture; Lee and Kurtz (1981), working in Oxford, UK, repeatedly passaged virus from an adult volunteer through primary human embryo kidney cells in the presence of trypsin. Although the virus did not cause cytopathic effect in these cells, its presence could be demonstrated by immunofluorescence. After six passages it was able to infect a continuous monkey kidney cell line (LLC-MK2 cells), again requiring the addition of trypsin and without the production of cytopathic effect. This cultivation method enabled the production of antigens and subsequently both polyclonal (Lee and Kurtz 1982) and monoclonal (Herrmann et al. 1988) antibodies to HAstV were produced. These led to the recognition of antigenic variation between viruses and five serotypes were identified (Kurtz and Lee 1984). This list has now reached eight serotypes of HAstV. There are thought to be at least two serotypes of bovine astrovirus (BAstV) but apart from this, serotypic variation amongst animal strains is unknown. Enzyme-linked immunoassays were also developed (Herrmann et al. 1990), and these are now available commercially superseding to a large extent diagnosis by EM.

The Oxford adapted astrovirus strains continue to form the basis for much astrovirus research and although these represent each of the five serotypes initially identified, the procedure required to produce more isolates is relatively cumbersome and the number of characterized clinical isolates remained small. This bottleneck was overcome with the finding that a continuous human gut cell line (CaCo-2) was able to support the growth of HAstV directly from stool specimens without the need for prior adaptation; most clinical samples could now be isolated routinely by conventional laboratory procedures (Willcocks et al. 1990).

Subsequently, molecular cloning techniques were applied to both the Oxford strains and isolates from elsewhere, leading to the complete sequence determination of several virus genomes. The information derived from this has in turn led to the development of more sensitive detection systems using the reverse transcription-polymerase chain reaction (RT-PCR). All these advances have in turn fed an increase in our understanding of astrovirus genomic structure and replication strategy that ultimately led to the recognition of the unique identity of these agents and to the definition of a new family of viruses – the *Astroviridae* (Monroe et al. 1995).

CLASSIFICATION

In the 1970s, the application of EM to human stools revealed a number of small round viruses. These were originally classified according to their morphology and in 1982, Caul and Appleton proposed an interim classification scheme dividing them into 'featureless' and 'structured' particles. The featureless viruses included the enteroviruses, parvoviruses, and parvovirus-like particles, whilst the 'small round structured viruses' included the astroviruses, human caliciviruses (now termed sapoviruses) and the Norwalk-like viruses (now termed noroviruses). The 'structured' group was further divided into smooth-edged particles (the astroviruses) and those whose particles had a ragged outline (the sapo- and noroviruses). Since this time, increased knowledge of the protein composition and replication strategies of these viruses has permitted their more detailed and definitive classification. Astroviruses and human caliciviruses were soon recognized as distinct entities and the term small round structured virus (SRSV) was then used simply to refer to noroviruses.

Historically, astroviruses were identified as such simply from their morphology. Virus particles were nonenveloped and were thought to contain a single-stranded, presumptive positive-sense RNA genome but little more was known about them. These features are shared by two other families of animal viruses (the *Picornaviridae* and the *Caliciviridae*). Astroviruses were better defined when the growing database of their properties enabled their ready differentiation from other virus families. Features of polypeptide composition and genome structure were used to distinguish astroviruses from those other families above and thus permit their formal classification as a distinct virus family, the *Astroviridae* (Monroe et al. 1995). In common with modern trends in virus taxonomy, astroviruses are increasingly defined and grouped according to their genomic sequences; indeed, avian nephritis virus (ANV) was first isolated in 1976 but it was not until 2000 that molecular

Table 1 *Human and animal astroviruses*

Genus	Species	Serotypes	Host	Disease	Abbreviation
Mamastrovirus	*Human astrovirus*	8	Humans	Gastroenteritis	HAstV
	Bovine astrovirus	2	Cattle	None	BAstV
	Ovine astrovirus	1	Sheep	Gastroenteritis	OAstV
	Porcine astrovirus	1	Pigs	Gastroenteritis	PAstV
	Feline astrovirus	1	Cats	Gastroenteritis	FAstV
	Canine astrovirus[a]	1	Dogs	Mild enteritis	CAstV
	Murine astrovirus[a]	1	Mice and other rodents	Diarrhea	MAstV
Avastrovirus	*Duck astrovirus*	1	Ducks	Hepatitis	DAstV

	Avian nephritis virus	1	Chickens	Acute nephritis	ANV

a) Tentative member of the *Astroviridae* awaiting molecular characterization.

cloning and sequence determination of the virus genome indicated that it should be classified within the *Astroviridae* (Imada et al. 2000). At first only one genus (*Astrovirus*) was recognized within the family. As sequence data accumulated, it became clear that the astroviruses obtained from mammals resembled each other more closely than those newly characterized viruses isolated from birds. The avian viruses likewise appear to be more closely related to each other than to astroviruses of mammals. Thus the *Astroviridae* have now been divided into two genera, *Mamastrovirus* (mammalian viruses) and *Avastrovirus* (avian astroviruses). The members currently assigned to each genus are listed in Table 1. Sequence comparisons such as these have the potential to illuminate much of the history of this virus family and this matter is discussed again under sequence phylogeny (see below).

BIOPHYSICAL PROPERTIES

Astrovirus particles are nonenveloped and have a buoyant density of between 1.34 and 1.40 g/ml in cesium chloride. HAstV particles have been reported with densities of 1.35–1.37 g/ml (Caul and Appleton 1982; Kurtz and Lee 1987; Willcocks et al. 1990; Matsui et al. 1993). Porcine astrovirus (PAstV) has been reported to have a buoyant density of 1.34–1.35 g/ml (Shimizu et al. 1990) and ovine of 1.38–1.40 g/ml. Aggregates of OAstV produced two peaks on cesium chloride density sedimentation: 1.365 and 1.39 g/ml (Herring et al. 1981). Similarly two distinct bands of 1.32 and 1.34 g/ml (Willcocks et al. 1990) and 1.33 and 1.37 g/ml (Matsui et al. 1993) were obtained using HAstV grown in vitro. Since the polypeptide composition of each band appeared identical in both cases, it had been speculated that the material of lower density consisted of empty virions. This was confirmed when Matsui and colleagues analyzed both peaks by hybridization analysis and showed that the lower density material contained no viral RNA (Matsui et al. 1993).

In common with other nonenveloped viruses, astroviruses show the expected resistance to lipid solvents such as chloroform and are able to resist a variety of detergents (non-ionic, anionic, and zwitterionic). They are relatively resistant to inactivation by chlorine, titer is not reduced at levels below 30 p.p.m. of free chlorine. The virus can withstand heating to 60°C for 5 but not for 10 minutes (Kurtz and Lee 1987). As enteric viruses, they also display resistance to inactivation at acid pH, although stability is actually quite broad and the viruses withstand a range of pHs from 2 to 11 (Kurtz and Lee 1987). Amongst the enteric viruses their general stability appears second only to hepatitis A virus (Carter and Adams 2000) and they persist well in the environment. These properties have an important influence on the potential routes for transmission of the virus and this is discussed below.

MORPHOLOGY

Electron microscopy

HAstV particles of 'typical' morphology were originally reported as approximately 28 nm in diameter with a clearly defined margin and a characteristic star-like motif in their center. However, the characteristic star-like motif is visible only on some 10 percent of the virions (Figure 1) – or fewer in some preparations (Madeley 1979). The stellate structures are five- or six-pointed, but neither of their centers is penetrated by stain. Consequently both stars have a characteristic solid white center in electron microscopy (EM). This contrasts with the six-pointed 'star of David' feature visible on the surface of caliciviruses when viewed along their threefold axis of symmetry. The surface features of

caliciviruses are ring-like hollows in which stain can accumulate. Calicivirus stars thus have a dark center surrounded by darker patches (Carter and Madeley 1987). It is not clear how the astrovirus star motifs are produced but insight may come from recent analyses of frozen particles using the technique of cryoelectron microscopy.

Astrovirus particles are usually attributed a smooth margin; however, in many micrographs there are indications of spike-like protrusions. Furthermore, particles are often present in very large numbers in stool samples and can sometimes be seen in paracrystalline arrays. Even when packed closely together, the edges of the particles seem not to make contact and it has been suggested that this even spacing between the virions could imply the existence of surface projections beyond the resolution of the electron microscope (Risco et al. 1995).

Particle size differs depending on the virus; OAstV has been reported to have a diameter of 29 nm (Gray et al. 1980), BAstV had an average diameter of 30 nm (but varied between 27 and 35 nm) (Woode et al. 1984). Interestingly, cell culture grown virus particles appear to be slightly larger, bovine astrovirus serotype 2 propagated in primary bovine kidney cells was 34 nm in diameter (varied between 30 and 37 nm) (Aroonprasert et al. 1989). This difference in diameter found between viruses propagated in cell culture and those derived from the natural host is also seen in HAstV and in general, HAstV particles grown in vitro and released from cell cultures appear less distinct and more ragged-edged than those observed in stool preparations. In fact, their average diameter has been reported to be as large as 34 nm for particles derived during the first five passages in CaCo-2 cells and such particles exhibited a remarkable similarity to caliciviruses in appearance (Willcocks et al. 1990; Risco et al. 1995). Viruses of more classical appearance were observed in later micrographs. Risco and colleagues (1995) similarly described virus released from LLC-MK2 cells and visualized in the electron microscope by negative staining as having a yet larger particle diameter (41 nm) and exhibiting a clear layer of surface spikes as suggested above.

Studies by Risco and colleagues (1995) also shed some light on this variability in appearance. These workers found that the larger particles shed from cell culture could be induced to display star-like motifs after a brief exposure to alkali (pH 10 for 10 minutes). Exposure like this is not likely under conditions of natural infection or sample collection, and most EM stains are acidic, but nonetheless local alkaline concentrations might conceivably occur during sample preparation and grid drying. The atypical larger particles were also infectious and it was proposed that these larger particles with the surface projections may represent the true native form of the virus, and the so-called 'typical' particles bearing surface stars might result from artifacts during preparation. However, it should be borne in mind that the gut is a complex environment; although astroviruses can be grown in CaCo-2 and LLC-MK2 cells, it is likely that neither mimics exactly the true host cell, the enterocyte. Similarly, production of infectious virus requires supplementation with a protease (trypsin) and capsid protein processing appears to proceed both inside and outside the cell and may involve several stages (see below). Perhaps other extracellular factors are needed to allow released virions to 'mature' fully, although present in the intestinal lumen these would be absent in cell cultures. Consequently, it is not clear at present whether the star-bearing astroviruses represent an artifactually rearranged ragged-edged particle, or whether the ragged particles might represent partially matured forms of those showing surface stars. However, it is clear that both types are infectious and that this variation may well have affected some of the EM-based studies of virus prevalence.

Cryo-electron microscopy

Cryo-electron microscopy uses computer analysis of digitized images of hydrated virus particles to generate an electron density map and eventually a three-dimensional reconstruction of the particle. The technique is powerful and recent data have been obtained using Oxford adapted virus grown in LLC-MK2 cells. The final reconstructions (Figure 2) show that astrovirus particles consist of a smooth but rippled icosahedral capsid some 33 nm in diameter. The ripples do give a faint indication of star-like patterning on the capsid surface but this is not a prominent feature in these images. Thirty dimeric spikes arise from this capsid and are situated at the twofold axes of symmetry. These extend some 5 nm from the particle surface to give an overall diameter around 41–43 nm. Little detail was obtained concerning the structure of the RNA within the particle but it appeared to adopt a partially icosahedral confirmation.

THE VIRION-ASSOCIATED PROTEINS

The polypeptide composition has been determined for several serotypes of HAstV as well as the ovine and porcine viruses. The results have shown heterogeneity both in the number and the size of the structural proteins. Initial studies on OAstV found two polypeptides of about 33 kDa (Herring et al. 1981), Shimizu and colleagues (1990) purified PAstV grown in cell culture in the presence of trypsin and identified five polypeptides (of 39, 36, 31, 30, and 13 kDa).

The protein composition of various serotypes of HAstV has been investigated. All were analyzed following propagation in the presence of trypsin. Kurtz and Lee (1987) identified proteins of 36.5, 34, 33, and 32 kDa in an HAstV-4 isolate and later Kurtz (1989) found proteins of 34, 33, 26.5, and 5.2 kDa in HAstV-1.

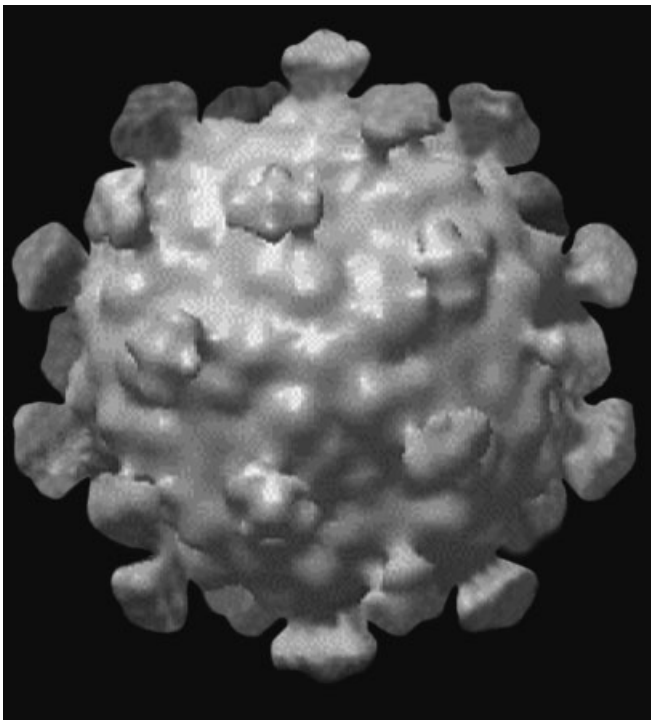

Figure 2 *Cryo-electron microscopic reconstruction of cell-culture-grown human astrovirus (resolution 2.4 nm). Structural predictions are derived by mathematical amalgamation of digitized images of frozen hydrated particles observed under the EM. The reconstruction shows surface projections rising from a smoothly rippled capsid surface. A five-pointed star-like feature is visible as a raised area in the center of the capsid surface. Image reproduced (with permission) from Matsui et al. 2001. We thank Dr S. Matsui and Dr M. Yeager for provision of this illustration.*

The small protein has never been confirmed but this may be due to variation between isolates or to differences in the polyacrylamide gel analysis system used. Willcocks and colleagues (1990) examined a serotype 1 astrovirus propagated in CaCo-2 cells and found proteins of 33.5, 31.5, and 24 kDa. Monroe and colleagues examined an HAstV-2 isolate adapted to growth in LLC-MK2 cells and found a similar pattern with proteins of 31, 29, and 20 kDa when the virus was propagated in the presence of trypsin (10 μg/ml). When trypsin was absent, virions contained a single protein of 90 kDa. Treatment of these virions with trypsin restored the normal pattern of polypeptides, confirming that the 90 kDa protein was an immature precursor to the normal forms (Monroe et al. 1991b). These reports have been combined to suggest a consensus protein composition for HAstV, although the actual sizes seem to vary with strain (Willcocks et al. 1992; Monroe et al. 1995). HAstV were thought to contain at least three structural proteins. Together the sum of their molecular masses suggested that they would account for almost all of the structural protein precursor. Two of these proteins formed a doublet on polyacrylamide gel analysis around 33 kDa, whilst the third was smaller and variable in size between isolates. This protein was not always detected, and was shown to be stripped from the virion by detergent treatment, which suggested that it may be loosely associated on the surface of the particle and thus be easily lost (Willcocks et al. 1990). Recently, Belliot and colleagues compared structural protein sizes in HAstV 1–5 and reconfirmed the basic pattern above; the largest two proteins varied very little between serotype and were always seen as a doublet of about 33 kDa. The third protein was consistently observed and varied between 25 and 28 kDa. This protein was largest in HAstV-2 and HAstV-4 and most variable in size amongst HAstV-5 isolates (Belliot et al. 1997a). The origin of these proteins is discussed below.

GENOME ORGANIZATION

The astrovirus genome consists of a single strand of positive-sense RNA of approximately 6 800 nucleotides, the 3′ terminus is polyadenylated (Jiang et al. 1993; Lewis et al. 1994; Willcocks et al. 1994b). The structure of the 5′ terminus is not known but it is anticipated that it is covalently linked to a small virus-encoded protein (VPg) as has been found in the calici- and picornaviruses.

The complete nucleotide sequences were first determined for HAstV serotypes 1 [Oxford reference strain adapted to growth in LLC-MK2 cells (Lewis et al. 1994) and Newcastle strain isolated in CaCo-2 cells (Willcocks et al., 1994b)] and 2 (Oxford reference strain; Jiang et al. 1993). All astrovirus genomes sequenced to date (including those of animal strains) show the same basic

organization. The RNA contains three sequential open reading frames (ORF) termed 1a, 1b, and 2 (Figure 3) and has a short nontranslated region at each end of the genome (approx. 85 bases at the 5′ end and 83 at the 3′ end). The sizes of these ORFs for representative types of astrovirus are given in Table 2. The nonstructural proteins are encoded in the 5′ section of the genome in ORFs 1a and 1b; the structural proteins are specified by ORF 2. However, whilst both ORF 1a and ORF 2 possess 5′ initiation codons in a good context for activity (Kozak 1989), and whilst ORF 1a closes at a termination codon, there is no obvious start codon for ORF 1b and no separate mRNA for this region has ever been observed. ORF 1b is encoded in the −1 frame relative to ORF 1a, and examination of the 71 nt region of overlap (Figure 4) revealed features resembling the translational frameshifting elements seen in other virus families (e.g. the retroviruses (Jacks et al. 1988), coronaviruses, and arteriviruses (Bredenbeek et al. 1990)). These features comprised a 7 nt AU-rich sequence typical of 'slippery' sequences at which translating ribosomes could move back one base into ORF 1b. Slippery sequences alone have little effect and all are combined with features of strong secondary structure. In the astroviruses this is a stem–loop rather than a pseudoknot (Jiang et al. 1993; Lewis et al. 1994; Willcocks et al. 1994b). These features are conserved in all sequences determined to date. Mapping studies have supported the existence of the predicted secondary structures (Marczinke et al. 1994). Testing of this region of the RNA by translation in vitro has confirmed that it does direct −1 ribosome translation frameshifting at the ORF 1a/1b junction with an efficiency of approximately 5 percent in vitro (Marczinke et al. 1994). This efficiency is about the same as that seen in retroviruses, but experiments in which the same signals were introduced into living cells indicated that frameshifting may be rather more efficient (25–28 percent) when translation takes place inside the cell (Lewis and Matsui 1996). Frameshifting ribosomes avoid the termination codon that closes ORF 1a and progress instead into ORF 1b. The product is an ORF 1a/1b fusion protein. Since not all ribosomes slip, this mechanism results in the manufacture of rather more ORF 1a products than those of ORF 1b. This latter frame encodes the virus RNA-dependent RNA polymerase which may be required in smaller amount. Thus the frameshifting events may be viewed as a refinement in the replication process, minimizing production of unnecessary RNA polymerase without requirement for a separate mRNA.

Replication of the virus

Replication of astrovirus is relatively poorly understood although the derivation of infectious clones of HAstV-1 (Geigenmuller et al. 1997) and ANV (Imada et al. 2000) should enable further analysis of the astrovirus life cycle and determination of structural features essential for replication and encapsidation.

The cell-surface receptor for astroviruses has not been identified; experiments with polarized gut epithelial cells (CaCo-2) have suggested that the receptor may be located on the basolateral rather than the apical membranes in this case (Willcocks et al. 1992). This appears unusual at first sight, but other enterically infecting viruses such as murine reovirus also show such

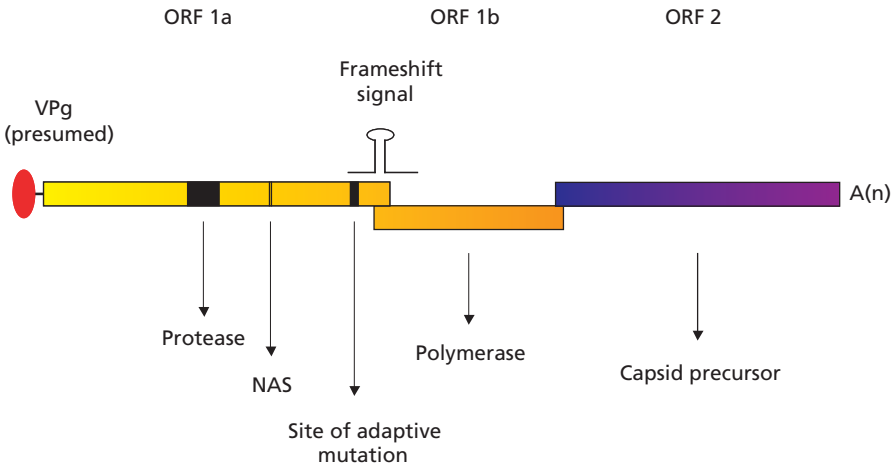

Figure 3 *Genome organization of human astrovirus. The basic three-open reading frame structure of* HAstV-1 *is illustrated (not to scale). A presumptive VPg is indicated at the 5′ terminus but its presence has not been formally demonstrated and the poly(A) tail is indicated at the 3′ terminus. The slippery sequence/stem–loop structure driving the frameshifting expression of ORF 1b is indicated at the overlap of ORFs 1a and 1b. These ORFs encode the virus nonstructural proteins and are both expressed from the genome. ORF 2 specifies precursors to virion structural proteins and is expressed from a subgenomic mRNA. The relative positions of functional motifs and other features of interest are indicated. Protease, site of virus serine protease; NAS, location of the bipartite nuclear addressing sequence; Site of adaptive mutation, location of repetitive sequences apparently deleted between strains and that may assist growth in some cell types.*

a) Sequence reveals 60 additional residues at the N terminus preceding the usual start sequence MASK. . . . It is not known if these are present in the astrovirus mRNA and consequently whether they are translated to protein. Similar sequences present in some strains of HAstV-1 are not transcribed into subgenomic mRNA.

a distribution of receptors. In that case it is believed that virus is taken up whole through the M cells overlying the Peyer's patches, and released on the other side, so gaining access to the basolateral cell surfaces. In this regard it may be significant that BAstV has an affinity for M cells (see below). Cell penetration proceeds via absorptive receptor-mediated endocytosis. Virus entry to the cytoplasm is presumably triggered by pH decrease in the endosome since procedures that elevate intra-endosomal pH have been shown to reduce virus infection (Donelli et al. 1992). The astrovirus genome is infectious if transfected into susceptible cells so it is assumed that translation of the incoming genome is sufficient to initiate the replication process. Full-length transcripts of a cDNA clone of the virus are also infectious on transfection but a synthetic cap structure must be added. This result is reminiscent of that obtained for the caliciviruses (Sosnovtsev and Green 1995) and suggests that some structure at the 5′ terminus (presumably a VPg) is required to initiate translation and that the role of this structure can be substituted by a cap. Proteins are generated from the genome by direct translation to express ORF 1a and via a −1 ribosomal frameshifting event to express ORF 1b. Processing of the polyproteins thus produced is described below.

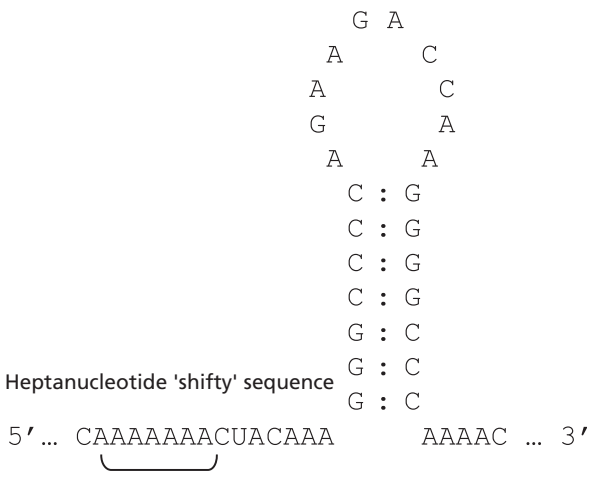

Figure 4 *Frameshift signal derived from* HAstV-1. *The sequence illustrated shows the A-rich heptanucelotide slippery or shifty sequence preceding the stable stem–loop structure. The stem is highly stable and GC-rich; sequence of the stem and the loop appear less important than the overall stability of the structure (Marczinke et al. 1994).*

There have been reports of a nuclear involvement in both BAstV and HAstV replication. Aroonprasert and colleagues (1989) studied BAstV infection in vitro using immunofluorescent antibodies and found fluorescence initially in the cytoplasm of infected cells, followed shortly by brilliantly fluorescing intranuclear granules, suggesting nucleolar involvement. Similarly, experiments

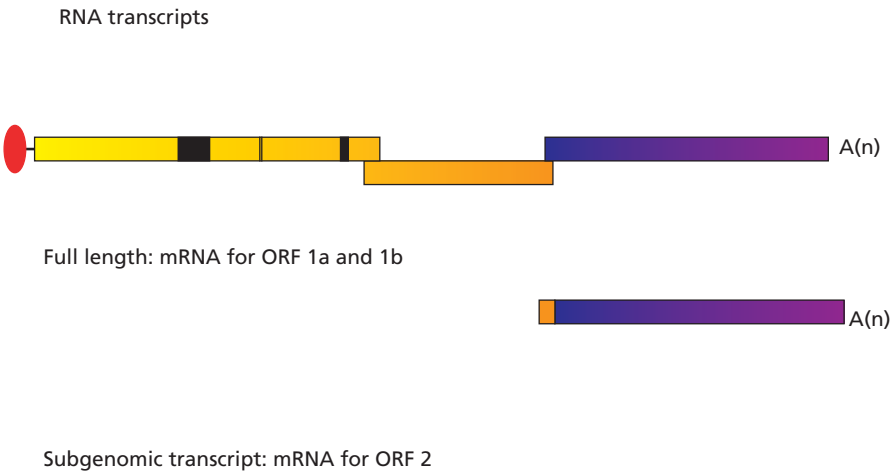

Figure 5 *Astrovirus-induced intracellular RNA. Full-length genome is present and acts as mRNA for ORFs 1a and 1b. A subgenomic mRNA is also synthesized to express the virus ORF 2 proteins. This is co-terminal with the virus genomic 3′ end and extends partially into ORF1b sequences. However, these precede the initiation codon and are not translated. In some viruses, ORF 2 in the genome is potentially longer than the subgenomic mRNA. In these cases any potential initiation codon (s) opening ORF 2 in the genomic RNA are usually in a poor context for activity and are not transcribed into the subgenomic mRNA. The subgenomic mRNA thus presents the ORF 2 initiation codon in the best context for activity as the first such codon in the message. Translation commences with the sequence 'M A S K ---' in almost all cases.*

studying HAstV replication in LLC-MK2 cells showed fluorescence in the nucleus at relatively late times in infection (W.D. Cubitt, personal communication). This fluorescence could suggest movement of structural protein to the nucleus since it has been detected with sera raised to the capsid protein. However, early cloning experiments used such sera to select clones expressing virus antigen (Matsui et al. 1993) and this approach led to the identification of regions specifying the so-called immunoreactive epitopes. Although one of these was derived from the capsid protein as expected, another was surprisingly located in the nonstructural genes close to the nuclear locating signal. When sera were raised to this part of the nonstructural protein, they also reacted with infected cell nuclei (Willcocks et al. 1999). The role of the nucleolus or nucleus in astrovirus infection is not known but replication is not affected by actinomycin D and thus DNA-directed information flow is presumably not required.

A second viral mRNA is also found during astrovirus replication (Monroe et al. 1991b); this subgenomic RNA is approximately 2 800 bases long and is also polyadenylated. It has been found by hybridization and sequence analysis to be co-terminal with the 3′ end of the genome (Matsui et al. 1993; Willcocks and Carter 1993) and is also believed to bear a VPg at its 5′ end (Figure 5). The subgenomic RNA has been found only in infected cells and does not become packaged into virus particles. During infection it is synthesized in five- to tenfold molar excess over the genomic RNA, presumably to allow synthesis of structural proteins in larger quantities than the nonstructural (Monroe et al. 1993). Since this RNA is not present in the virus, it must be generated from the incoming full-length genomic RNA; however, little is known of RNA synthesis by this virus. Promoters have not been characterized and it is not known whether the subgenomic mRNA is subsequently replicated independently via its own separate negative-strand template, or produced only from the full-length antigenome. The 5′ terminus of the subgenomic RNA has been mapped (Monroe et al. 1993) and primer extension analysis reveals the bulk of the product to commence at position 4 359 in the sequence (coordinates refer to HAstV-1). Although the bulk of the molecule does indeed extend in a 3′ direction from this position, a small fraction of the product is slightly longer by 12 or 16 bases (Willcocks and Carter 1993).

Early in infection, capsid antigen is detected in the cytoplasm as a diffuse fluorescence in the perinuclear area. As infection proceeds this becomes more granular, and EM shows dense deposits of virus capsids in these areas (Aroonprasert et al. 1989). Cytopathic effect is not well observed because the trypsin required to allow the particles to mature causes detachment of the cells such that cytopathic effect is not visible. The exception to this has been in some CaCo-2 cell cultures where a shriveling and rounding of the cells can be seen. In this case cytopathic effect is usually limited to the margins of the cell sheet (Willcocks et al. 1990). This is presumably because receptors are located on the basolateral membranes of the cells and the virus has ready access to these only at the edges of the monolayer. Most others are presumably shielded below the tight junctions that bind the cells together. Virus is presumed to be released by cell lysis.

PROTEIN CODING AND EXPRESSION

ORFs 1a and 1b specify the virus nonstructural proteins; the arrangement of the sequences for which a potential role has been identified is given in Figure 3. ORF 1a has the potential to specify a 101 kDa protein that, in common with other positive-strand RNA viruses, is subsequently cleaved to release functional processed molecules. Both the polyprotein and a number of cleavage products have been identified inside cells, although function has not been allocated to all of them. Sequence analysis has revealed the presence of a chymotrypsin (3C)-like serine protease (Jiang et al. 1993); this is in contrast to the picorna- and caliciviruses which have a cysteine residue at the active site of their 3C protease. However, no sequence motifs indicative of RNA helicase, methyltransferases, or papain-like proteases have been detected in astroviruses. It is possible that small RNA viruses of this type do not require a helicase for efficient replication (Koonin 1991b; Jiang et al. 1993). It has been suggested that astrovirus may encode a VPg, based on the absence of a methyltransferase and the similarity of the polymerase to those of other VPg-containing viruses. Sequence analysis has indicated that it might be encoded upstream of the protease but VPg has not been observed experimentally (Matsui and Greenberg 1996). Towards its C-terminus, ORF 1a contains a bipartite nuclear localization signal (Willcocks et al. 1992; Jiang et al. 1993). Antisera raised to this region of the polyprotein have shown that nonstructural proteins do enter the cell nucleus during infection (Willcocks et al. 1999), but the purpose of this movement is not clear. This region of ORF 1a is also the site of a mutation that seems to accompany adaptation of HAstV to growth in continuous cell lines of nongut origin (e.g. LLC-MK2 cells). The Oxford adapted viruses were obtained by serial passage in primary human embryo kidney. During this process the host cell range of the virus became altered. Comparison with samples of the same virus that had been passaged in volunteers rather than human embryo kidney, cells showed that the cell-adapted virus contained a deletion of 45 nt. This removes a partially repetitive 15 amino acid sequence. Isolates made directly in gut cell lines (e.g. CaCo-2 cells) did not contain this deletion (Willcocks et al. 1994a). It has been suggested that this deletion might improve 'fit' between a virus protein and a cellular protein with which it must interact, thus extending host cell range. However, other features of this region also seem variable between strains and so the extent to which this modification represents adaptation to a particular host cell type rather than a coincidental or strain-related variation is not fully understood.

ORF 1b encodes a 59 kDa polypeptide whose amino acid sequence is that of an RNA-dependent RNA polymerase; it contains all the motifs typical of a polymerase belonging to supergroup I (Jiang et al. 1993). This group includes polymerases of the picorna- and caliciviruses, as well as some plant viruses (such as the bymoviruses and potyviruses), although the similarities between astroviruses and the plant viruses in this region do not necessarily indicate a common origin for the viruses (Koonin 1991a).

ORF 2 encodes the virion structural proteins and is expressed from a subgenomic mRNA that is 3′ co-linear with the genome (Monroe et al. 1993; Willcocks and Carter 1993). The structural proteins are produced as a precursor (90 kDa), which is then proteolytically cleaved. This protein has a well-conserved N terminus which is highly basic, and contains a serine/arginine repeat motif (Jonassen et al. 2001). This is similar to the basic region found in some coronaviruses (those related to transmissible gastroenteritis virus), and is also reminiscent of some plant viruses where such a sequence is involved in RNA binding (Carter 1994). By contrast, the 3′ end of ORF 2 specifies a highly acidic region. The function of these two areas is not known, but it is likely that these regions of strong charge localization do play a role in protein–protein interactions or protein–RNA interactions.

A highly conserved 35 nt stem–loop structure is located near the ORF 2 stop codon in all the astrovirus sequences examined to date (except that of TAstV-2). This feature straddles the termination codon and is formed from both translated and nontranslated sequences. The function of this structure is not known, but it is likely to be vital to the virus. Any change in one nucleotide of the stem structure is always accompanied by a compensatory mutation in the other strand of the stem such that base pairing and thus secondary structure is maintained (Jonassen et al. 1998).

Processing of nonstructural proteins

The nonstructural proteins are generated from two polyproteins corresponding to ORF 1a (101 kDa) or the ORF 1a/1b fusion resulting from ribosomal frameshifting during translation (160 kDa). The processing of these proteins remains to be fully elucidated but several workers have now examined processing either in infected CaCo-2 cells, transfected baby hamster kidney (BHK) cells or in vitro. A synthesis of the resultant data is presented in Figure 6.

Processing has been examined during productive infections of CaCo-2 cells using sera raised to specific sections of the nonstructural protein ORFs. Sera recognizing the C-terminal third of ORF 1a (residues 643–920 in HAstV-1) detected multiple cleavage products; the complete ORF 1a product was not observed, the largest protein being only 75 kDa. This indicated that some 26 kDa had been rapidly cleaved from the N terminus of ORF 1a and could not be detected using this serum. The 75 kDa protein appeared to be further cleaved,

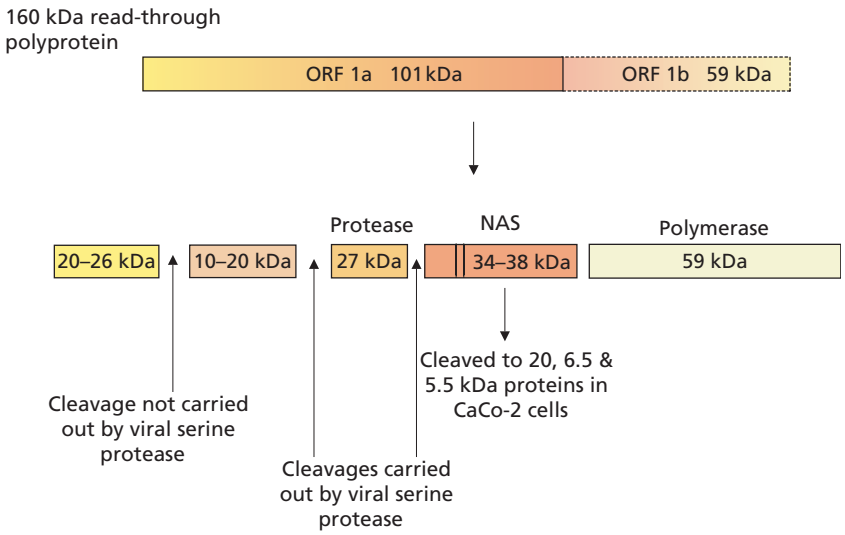

Figure 6 *Processing of astrovirus nonstructural proteins. Here the processing of the ORF1a/1b fusion generated by read-through translation of both ORFs is illustrated; 20–26 kDa is cleaved from the N terminus by a nonviral protease soon after translation (whilst other cleavages are performed by the virus-encoded enzyme). This releases the 27 kDa protease molecule and a presumptive second protein that has not been directly observed. The third section released from ORF 1a (34–38 kDa) includes the bipartite nuclear addressing signal (NAS) and is further cleaved to at least three products 20, 6.5, and 5.5 kDa in size. The ORF 1b product (polymerase) is believed to be cleaved at or near the frameshift position and is not markedly cleaved subsequently.*

producing a 34 kDa C-terminal product that could be detected by the serum used. Any other product(s) that derived from the N terminus of the molecule were not detectable by this method. The 34 kDa molecule appeared to be unstable and did not accumulate to high levels in the cell; instead it appeared to be processed to cleavage products of 20, 6.5, and 5.5 kDa that were observed to accumulate. The proteins that would be recognized by this serum would include any that contain the nuclear localization signal, and these were identified in the cell nucleus (Willcocks et al. 1999).

ORF 1a sequences have also been expressed in BHK cells transfected with expression constructs containing ORF 1a (Geigenmuller et al. 2002a). These workers also observed a cleavage near the N terminus, removing in this instance a 19 kDa section. This cleavage also took place if the virus protease was inactivated, thus confirming that it is not mediated by this enzyme and is probably a host-cell-specified event. Further processing was dependent on a functional viral protease and led to a product of 27 kDa that spanned the serine protease motifs. This corresponds to the 27 kDa protein identified in astrovirus-infected CaCo-2 cells and which can now be identified as the virus protease itself.

Gibson and colleagues (1998) reported the in vitro expression of both the full-length ORF 1a polyprotein and that of the combined ORF 1a/1b but presented no information on processing. A second study examined processing in vitro using antisera raised to synthetic peptides; a single autocatalytic event was observed in the ORF 1a polyprotein. This yielded an N-terminal 64 kDa and a C-terminal 38 kDa product. This cleavage was accomplished by the virus-specified serine protease since mutation of the serine at the active site obviated this event (Kiang and Matsui 2002). The 38 kDa protein is probably analogous to the 34 kDa protein identified in CaCo-2 cells and their nuclei. The removal of 26 kDa from the N terminal was not observed, indicating again that this may be a host-cell-dependent cleavage.

Willcocks and colleagues (1999) also detected synthesis of the polymerase (ORF 1b product) in CaCo-2 cells using sera raised to the expressed ORF 1b protein. A single product of 59 kDa was detected. This is approximately the size expected for the whole of ORF 1b (786 aa). This suggests that little if any internal cleavage takes place in the polymerase and similarly that most or all of ORF 1a is effectively removed when the fusion protein is processed.

Processing of structural proteins

The astrovirus structural protein is translated from ORF 2 as a 90 kDa precursor protein and it has long been recognized that trypsin plays a vital role in cleavage of this precursor (Monroe et al. 1991b). Willcocks and colleagues (1990) showed that particles released in the absence of trypsin were non-infectious. Bass and Qui (2000) confirmed this finding and showed that such particles contained only minimally processed capsid precursor protein; 71 amino acids were cleaved from the N terminus intracellularly to generate a 79 kDa capsid precursor from which particles were formed. Treatment of these particles with trypsin after release led to the formation of three structural proteins and increased infectivity by 50 000–100 000-fold. Other workers have

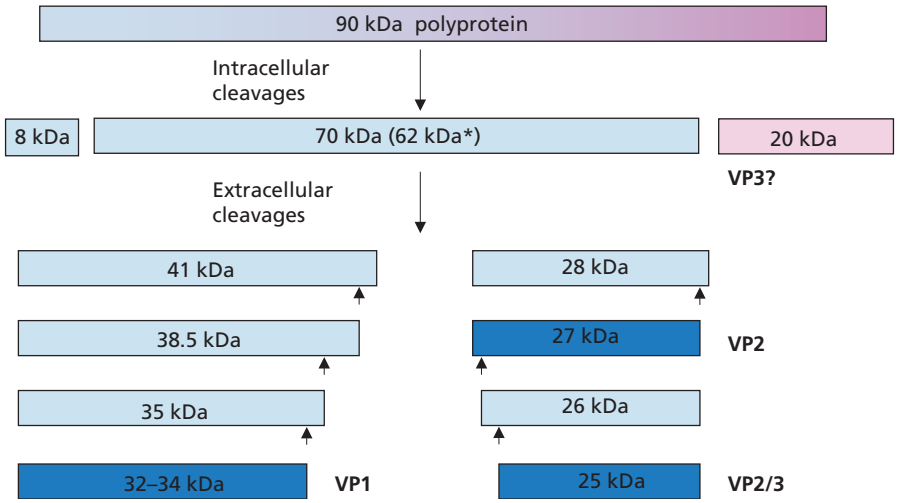

Figure 7 *Processing of astrovirus structural proteins. The illustration attempts to bring together data from a variety of sources, not all of which are compatible. Consequently the actual processing pathways used by any one virus may vary depending on either serotype of virus and/or host cell. In the model presented, primary translation generates a molecule of 90 kDa (VP90) that is subsequently processed. One report states that 8 kDa may be cleaved from the N terminus rapidly after translation (indicated by '*') but this does not appear to be general and does not occur in other systems where it has been sought. VP20 is cleaved from the C terminus and at least one report finds that this occurs intracellularly. In this case VP20 was not subsequently present in the virion (Mendez et al. 2002) and particles were formed exclusively from VP70. Other reports indicate that particles form from VP90 (and thus must include residues derived from VP20) (Geigenmuller et al. 2002b). Thus the backbone of the virion may indeed be formed from sequences contained within VP70 but the C-terminal residues contained within VP20 may be superficially located. Once cleaved (intracellularly or extracellularly), they may readily dissociate from the particles. Maturation of VP70 (or VP90 where particles are constructed from this protein) occurs extracellularly and is mediated by trypsin. Several sequential cuts are made and the efficiency of each may vary with both the strain of virus (and the accessibility of the scissile bond) and the activity of trypsin supplied in the growth medium. As a result, particle compositions may appear complex but VP32–34, and the overlapping proteins VP25 and VP27 may predominate (indicated in deeper color). Differences in the extent of maturational cleavage could also explain the lack of stoichiometric relationship observed in some preparations where levels of VP27 appear far lower than those of VP25. Past attempts to use a conventional nomenclature in which virus proteins are numbered VP1–3 are complicated. This nomenclature is best avoided since the proteins could be potentially assigned different names depending on the degree of cleavage and/or VP20 dissociation in any one preparation (indicated above).*

not observed this trimming of the N terminus and report structural proteins in the virion that extend completely to the N terminus of the protein. (Geigenmuller et al. 2002b; Mendez et al. 2002).

Determination of the cleavage sites and the manner of processing of virion proteins has been complicated by uncertainty as to the protein composition of the virions (see above). In a study of the Oxford HAstV-2 strain, Sanchez-Fauquier and colleagues (1994) found that the capsid precursor was cleaved to three polypeptides (34, 29, and 26 kDa) in the presence of trypsin. These sizes would account for almost all the structural protein precursor. However, N-terminal sequencing revealed surprising features. VP29 and VP26 were not distinct molecules. Instead, these moieties overlapped substantially; they shared a common C terminus and were both derived from the center of the precursor protein. The residues extending from the N terminus of the precursor to the N terminus of VP29 could form the 34 kDa protein (although this was not confirmed), but this analysis left the fate of some 27 kDa from the C terminal of the precursor protein unexplained. A further study of structural protein processing in HAstV-8 offered a possible explanation for these findings (Figure 7). Mendez and colleagues (2002) found that 20 kDa was cleaved from the C terminus of the capsid precursor intracellularly. This molecule was not detected in virions and its fate has not been determined. The remaining 70 kDa molecule was processed extracellularly and only to completion when high levels of trypsin (>100 μg/ml) were present. The 70 kDa polyprotein was cleaved firstly to 41 and 28 kDa products and subsequently the size of each was further reduced through a series of trimming cuts. Three products were prominent in preparations of virions; VP34 and two forms derived from VP28: VP25 and VP27. The relationship between these two molecules agrees with the findings of Sanchez-Fauquier et al. (1994). The variability in the detection of the third virion protein could then result simply from differing efficiencies of trypsin cleavage and this might also explain some of the earlier reports of multiple protein components in the virion.

However, this explanation also fails to provide a role for the C-terminal 20 kDa removed intracellularly from the precursor in these experiments. This section of the protein is highly variable in sequence between serotypes. This suggests exposure to host antibody selection pressure and thus implies a structural (or at least extracellular)

role. Furthermore, its presence on the same mRNA as the structural proteins would suggest that it is manufactured in similar amount. Geigenmuller and colleagues (2002b) infected CaCo-2 cells with mutant virus bearing a tag sequence at either the N or C terminus of the capsid protein. They also observed the removal of up to 20 kDa from the C terminus of the capsid precursor protein, but in this case the process was inefficient; the majority of the protein remained uncleaved regardless of the position of the tag. However, particles were observed in these cells, suggesting that C-terminal cleavage is not essential for particle formation and consequently C-terminal sequences can be incorporated at least into immature forms of the capsid inside the cell. Although these facts are suggestive of a structural role, this region has not been demonstrated in mature, extracellular virions by N-terminal sequence determination, indicating that it may be lost during particle maturation or sample preparation in the laboratory.

SEROLOGY

In the 1980s, Kurtz and Lee identified five serotypes of HAstV (HAstV-1–5) by immunofluorescence and immunosorbent electron microscopy (Lee and Kurtz 1982; Kurtz and Lee 1984). Each of these reference strains had been adapted to growth in LLC-MK2 cells (Lee and Kurtz 1981). Since then, three more serotypes have been recognized (HAstV-6–8); all were originally isolated in the UK (Lee and Kurtz 1994; Kurtz, unpublished data). However, they have remained uncommon in the UK. The HAstV are antigenically distinct from the animal viruses (Kurtz and Lee 1984); however, feline astrovirus (FAstV) is detected efficiently by enzyme-linked immunosorbent assay (ELISA) kits engineered using sera and monoclonal antibodies raised to HAstV.

In many viruses, genogroup analysis based on sequence phylogeny is superseding conventional classification by serotyping. Although genogroup analysis can be performed on any part (or the whole) virus sequence, serotyping by definition depends only on the structural proteins. For the most part, genogroupings are based on nonstructural sequences since these are well conserved and thus relatively easily accessed by PCR for sequence determination. In general, this type of analysis does give similar, if not identical, patterns regardless of the section of the genome used for analysis, but even so the potential for recombination events that might combine structural genes from one serotype with nonstructural genes from another should not be ignored. These problems can be largely overcome in the case of the astroviruses provided that the structural protein is used for genotyping. Noel and colleagues (1995) examined a short PCR product derived from ORF 2 of each serotype and showed that genotyping in this instance led to the same result as serotyping. Since then, additional capsid precursor sequences have become available, but the coincidence of the two types of grouping has been maintained. Wang and colleagues (2001) compared capsid precursor sequences of 46 strains of HAstV and found that the genogroups obtained corresponded exactly to the serotypes. Comparisons have shown that within any given serotype, where more than one ORF 2 complete sequence is available, the strains are more than 94 percent identical. By contrast, the highest identity level seen between serotypes was 75 percent between types 5 and 6 (Mendez-Toss et al. 2000).

Jonassen and colleagues (2001) examined variation within the capsid sequence and also found that the N-terminal half was well conserved, while the C-terminal portion was hypervariable with large inserts or deletions. Neutralizing monoclonal antibodies prepared to the astrovirus capsid have all been found to be specific to the VP29 protein encoded in the midsection of the capsid polyprotein (Bass and Upadhyayula 1997).

The largest protein, on the other hand, is more conserved, and a common epitope has been predicted from sequence analysis (Mendez et al. 2002). All the serotypes of HAstV are recognized by a single non-neutralizing monoclonal antibody produced by Herrmann and colleagues (1988). The monoclonal antibody is directed at the capsid protein (Lewis et al. 1994), but the site it recognizes has not been fully defined. Current data suggest that the antibody binds to two discontinuous regions of the capsid protein, both located in the largest protein VP34 between residues 82–115 and 215–260 (residue numbers given for HAstV-1 strain A2/88 Newcastle) (M.M. Willcocks et al., unpublished data). This monoclonal antibody has been used to develop a commercial ELISA for astrovirus and also reacts with FAstV.

SEQUENCE PHYLOGENY

Genome nucleotide sequences

The complete nucleotide sequences have now been determined for four serotypes of HAstV:

1. HAstV-1 both Oxford (Lewis et al. 1994) and Newcastle (Willcocks et al. 1994b) strains
2. the Oxford strain of HAstV-2 (Jiang et al. 1993)
3. HAstV-3 from Germany (Oh and Schreier 2001)
4. HAstV-8 from Mexico (Mendez-Toss et al. 2000).

Three of the avian astroviruses have been sequenced, two from the turkey [TAstV-1; (Jonassen et al. 1998) and TAstV-2 (Koci et al. 2000a)] and one from the chicken (ANV; Imada et al. 2000). One other mammalian virus, that of the sheep, has also been sequenced – OAstV (Jonassen et al. 2001). The sequence of the structural gene *ORF2* has been obtained for the remaining serotypes of HAstV: HAstV-4 (Willcocks et al. 1995), HAstV-5 (Wang et al. 2001; S.S. Monroe et al., unpublished data), HAstV-6 (M.M. Willcocks et al.,

I. Oishi et al., both unpublished data), and for HAstV-7 (Jonassen et al. 2001; Walter et al. 2001b). Structural gene sequences are also available for the feline (M.M. Willcocks et al., unpublished data) and porcine astroviruses (Jonassen et al. 2001; Wang et al. 2001).

An analysis of the nine complete sequences available showed that they could be divided into two groups (Figure 8), with one containing the mammalian astroviruses (OAstV being an outlier) and the second containing the avian astrovirus sequences. The same two groups were also derived using either ORF 1a or 1b alone for the comparison (Lukashov and Gouldsmit 2002). Comparison, by these authors, of all the available ORF 2 sequences groups all the HAstV serotypes together with the feline virus being most closely related to them, followed by the porcine, and with the ovine capsid sequence showing considerable variation from the other mammalian capsid nucleotide sequences. Again the avian astroviruses formed a separate cluster. The authors speculate that the topology of the phylogenetic trees suggests that cross-species transmission may have occurred during astrovirus evolution with a PAstV-like virus being passed to cats and then to humans. This sort of cross-species transfer occurring during virus speciation and over evolutionary time must be clearly distinguished from zoonotic infections whereby animal viruses may infect humans, although this may also occur (see below). Grouping of the structural proteins on the basis of their more conserved sections should indicate underlying relatedness between viruses and strip out the effects of antigenic variation driven independently by immune responses in different host species. When performed this way, FAstV was even more closely grouped with the human strains, again indicating an evolutionary relationship (Wang et al. 2001). A comparison based on ORF 2 amino acid sequences reached similar conclusions (Jonassen et al. 2001).

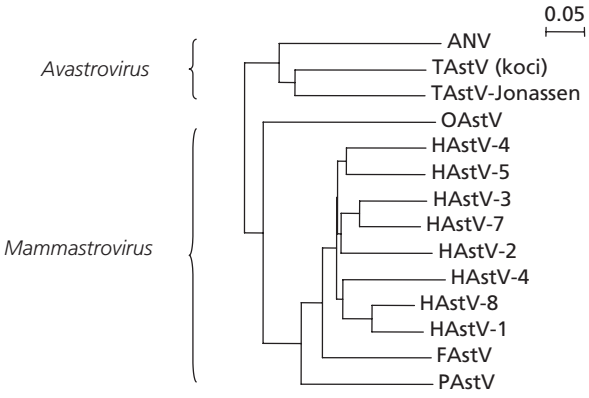

Figure 8 *Phylogenetic analysis of representative astrovirus capsid sequences. Sequences fall into two clear genogroups that have now been recognized as separate genera:* Mamastrovirus *containing sequences from mammalian viruses and* Avastrovirus *containing sequences from avian isolates. FAstV groups closest to human strains whilst OAstV is an outlier from the* Mamastrovirus *group.*

Analysis of virus sequences can always be complicated by the potential for recombination between genomes. The two phylogenetic groups identified above are not affected by these concerns, but recombination between human astroviruses can almost certainly take place. Four isolates of HAstV-5 from Houston, TX and Mexico City were analyzed at the junction of ORF 1b to ORF 2. These new isolates were closely related to serotype 3 in ORF 1b but closest to serotype 5 in ORF 2. These data, combined with the strong sequence conservation in this region seen in all HAstV serotypes, indicated a possible recombination site at the ORF 1b/ORF 2 junction (Walter et al. 2001a). Recombination events like this could exchange capsid protein genes between viruses in the case identified between serotypes of human virus, but presumably this could also exchange genes between an animal and a human virus under appropriate circumstances.

TRANSMISSION

Person to person

The virus is transmitted by the fecal–oral route and therefore spreads readily among babies and small children where infection is most common. There have been many reports of outbreaks in childcare facilities and schools (Lew et al. 1991; Mitchell et al. 1993, 1999b). Prevention or control of astrovirus infection in such settings is generally best achieved by careful attention to hygiene (hand washing, cleaning, or disposal of potentially contaminated items). It has been suggested (Abad et al. 2001) that astroviruses are able to survive on inert surfaces long enough for fomites to play a role in transmission of astrovirus diarrhea, and disinfection of any potentially contaminated surfaces, door handles, etc., is also required. The virus has been shown to be relatively resistant to disinfection by ethanol or isopropanol (Kurtz et al. 1980). It is also relatively resistant to inactivation by heat, acidification, detergent treatment, and treatment with phenolic, quaternary ammonium chloride, or benzalconium chloride-based products (Kurtz and Lee 1987). However, 70 percent methanol was found to decrease infectivity by 3 $\log_{10}$ and 90 percent decreased it to less than 10 infective units/ml and proprietary virucidal surface cleaners are effective. Since the virus is relatively temperature stable, attention should be paid to the operating temperature of bedpan washers. Infected individuals should be separated from those not infected and particular care should be taken to ensure that those who handle food do not continue to work while infected.

Foodborne

Foodborne transmission is not generally assumed to be significant in the case of astrovirus infection. This arises

since the bulk of astrovirus infections occur in the young, an age group where direct fecal–oral person-to-person transmission is more likely. However, foodborne transmission between adults is likely to be more significant, and although most individuals are likely to have had prior experience of astrovirus types 1 and 2 (with resulting protective or ameliorating antibody memory), many would not have encountered the rarer serotypes which could therefore induce symptomatic illness. Astrovirus outbreaks have been associated with the consumption of shellfish contaminated with sewage (Kurtz and Lee 1987). A recent study in France found that 17 percent of oysters sampled were contaminated with the virus; and that, when sampling was carried out in an area routinely impacted by human sewage, 50 percent of mussels examined contained detectable levels of viral RNA (Le Guyader et al. 2000). Mussels and cockles are generally cooked before consumption and regulations brought in to control hepatitis A virus contamination will also control astroviruses. Astroviruses have been associated with single-exposure outbreaks similar to those more usually associated with Norwalk viruses, but these seem relatively uncommon. These have been well studied in Japan where Oishi and colleagues (1994) reported data from a multi-school outbreak in Osaka; and Utagawa and colleagues (1994) reported three outbreaks associated with restaurants and schools. In each case, astroviruses were the organisms most frequently identified although other agents were also present in some samples from the outbreak. Consequently, the contribution of individual viruses to the overall pattern of these events is not completely clear. Nevertheless, the potential for widespread and significant astrovirus-induced foodborne illness must be acknowledged.

Astroviruses survive well in water (see below) and transmission from contaminated streams has been reported (Cubitt 1991). They are also relatively difficult to inactivate with chlorine (the normal method of rendering water potable) being considerably more resistant than poliovirus (Abad et al. 1997). If the virus survives chlorination, then further inactivation could be quite slow, astroviruses can persist for a long time in dechlorinated tapwater: after 60 days the infectivity was reduced by 3.6 logs when the water was maintained at 20°C and only 2 logs at 4°C (Bosch et al. 1997). Astrovirus has been detected in water samples from an area where a concurrent astrovirus-induced gastroenteritis outbreak had occurred (Pinto et al. 1996).

Environmental transmission

Until recently relatively little was known of the circulation of astroviruses through the environment and particularly through surface waters and water treatment systems. A recent survey of seawater bathers in the UK implied that astrovirus survived well enough to pose a risk of infection in coastal waters and the presence of virus in shellfish (above) is also indicative. Higher levels of gastroenteritis were reported by surfers compared to age-matched controls who did not sea-bathe. Of the surfers surveyed, 93 percent showed serological evidence of exposure to HAstV-4 compared to 39 percent of controls (Myint et al. 1994). Molecular methods have detected astroviruses in 21 percent of river water samples and 3 percent of Dam water samples in South Africa (D. Steele, personal communication). Virus was found in samples where all usual microbiological indicators of fecal pollution were absent or within acceptable limits implying that astrovirus may present a risk in samples that could be assessed as 'safe' by usual methods (Taylor et al. 2001). The stability of the virus means that particles survive well and are detectable in waters flowing both into and out of water treatment works, indicating that viruses survive at least some forms of water processing. A quantitative assessment of astrovirus in such waters found that titers of 4×10^5– 1.4×10^7 particles per 100 ml in the water flowing into treatment plants and levels of 6×10^2–9×10^4 per 100 ml in the treated water flowing out (P. LeCann, personal communication). Astrovirus (and enteroviruses) has also been detected in sludge (Chapron et al. 2000). Consequently, it is hard to avoid the conclusion that astroviruses represent a hitherto underestimated environmental contaminant. Given recent data from Koopmans and colleagues (1998) that exposure to one serotype carries little protective effect against infection by other serotypes, then adults will continue to be at risk from the higher serotypes to which they are only rarely exposed.

PREVALENCE

Even from the first small-scale studies it was apparent that HAstV infections are very common, exposure occurs early in life (at least to the more common serotypes), and seropositivity rises steeply in early childhood. A survey in the UK found that 64 percent of children had antibodies to HAstV-1 by 4 years of age and this figure rose to 87 percent by age 10 (Kurtz and Lee 1978). A more recent age-stratified assessment of seroconversion to types 1 and 6 in London showed that children rapidly seroconverted to type 1 as maternal immunity waned. Infections commenced around 5–6 months of age and by age 5 nearly 90 percent of samples were positive for type 1 antibody. Seroconversion to type 6 was seen to commence slightly later (7–11 months) and to rise more slowly, reaching only some 20 percent even by adulthood (Kriston et al. 1996). A similar study addressing seroconversion in the USA found again that seroconversion to type 1 occurred rapidly after loss of maternal antibody, reaching 94 percent by age 6–9 years. In this case infections by HAstV-3 were also studied and a similar pattern observed. Infections occurred during the same time frames as those by HAstV-1 but were less

frequent, with 55 percent of 6–9-year-olds remaining seronegative (Mitchell et al. 1999a). Midthun and colleagues (1993) found 45 percent of adults were seropositive for type 5 virus, 55 percent having presumably not contracted the virus. A seroprevalence survey in the Netherlands reached similar conclusions (Koopmans et al. 1998), finding antibodies to HAstV-1 in 91 percent; HAstV-2 in 31 percent; to HAstV-3 in 69 percent; to HAstV-4 in 50 percent and to HAstV-5 in 36 percent of persons sampled.

Several surveys have examined the incidence of astrovirus in diarrheal stools. In general, these fall into two classes: those using predominantly EM as the means of diagnosis, and those using alternative techniques (RT-PCR or ELISA). The former class generally report astroviruses at a frequency of 1–5 percent in diarrheal stools, whilst the latter find an increased prevalence and report values in the region of 5–15 percent. The second type of survey generally suggests that astrovirus is second only to rotavirus as a cause of enteric illness in children. A potential explanation of this discrepancy is addressed under diagnostic methods. Despite their differences, these surveys do reveal some underlying patterns, as follows.

First, where seasonality was detected, astrovirus incidence mirrored that of rotavirus. A peak of infection was observed in the winter months in Europe and the developed world (Guix et al. 2002; Lew et al. 1990; Maldonado 1996; Monroe et al. 1991a; Mustafa et al. 2000; Rodriguez-Baez et al. 2002; Sakamoto et al. 2000). Infection peaks in the rainy seasons elsewhere, e.g. Guatemala (Cruz et al. 1992) and rural Mexico (Maldonado et al. 1998). Infections in Japan showed a peak between March and April (Utagawa et al. 1994). The explanation of seasonality is not clear for any enteric virus, although it possibly involves contributions from a variety of factors. These may include: an increased efficiency of person-to-person transmission in colder weather (due to increased virus survival in the environment and more crowding in public places); the possibility of watercourse contamination (due to increased rainfall and blockage of drains, etc., by leaves); and even an increase in the levels of virus in filter-feeding shellfish consumed in the colder months.

Second, whilst co-circulation of different serotypes, and also of distinct genetic variants within a serotype, is often seen (McIver et al. 2000; Traore et al. 2000), serotype 1 is usually the most common virus detected, a finding expected from the seroprevalence studies above. Kurtz and Lee (1984) determined the serotypes of astroviruses acquired in the community in Oxford (UK) and found serotype 1 accounted for 77 percent of virus identifications in clinical samples. Serotypes 2–5 each accounted for 5–7 percent of the isolates. This was, however, a relatively small survey, but a more recent repeat (covering the period 1976–92) yielded similar data (Lee and Kurtz 1994). Serotype 1 was again the most common (65 percent), with all the other serotypes having much lower incidence (HAstV-2 and HAstV-4 both 11 percent; HAstV-3 9 percent; HAstV-5 2 percent; and HAstV-6 and HAstV-7 both less than 1 percent). These findings are repeated across the world, serotype 1 being the most common serotype found in surveys carried out in a variety of geographical regions (Australia – Palombo and Bishop 1996; Chile – Gaggero et al. 1998; Mexico – Mendez-Toss et al. 2000; Korea – Kang et al. 2002; and Spain – Guix et al. 2002).

Third, this relative prevalence of serotype 1 is not universally true. Some fluctuation in relative prevalence of the individual serotypes is observed. In the UK survey described above, serotype 1 was the most common throughout the period surveyed except in 1991 when serotype 2 was the most prevalent (Lee and Kurtz 1994). Analysis of the age-stratified seroprevalence studies in London also indicates that infection by serotype 1 viruses may have increased in the years since 1990–91 and a sharp decrease in the seroprevalence rates (from 90 to 50 percent) is observed in children above the age of 6 years. This suggests that infection was less common when these individuals were aged <12 months, the peak age period for acquisition of the virus. Evidence from seroconversion of seawater bathers (Myint et al. 1994) and from serotyping studies in Oxford (Willcocks et al. 1995) indicate that serotype 4 increased in prevalence in the UK in 1993. Similarly, HAstV-2 was found as the most common serotype in Mexico City in two reports (Guerrero et al. 1998; Walter et al. 2001b), and in Malawi, HAstV-1 and HAstV-2 were found in approximately equal incidence (Cunliffe et al. 2002).

In common with rotavirus and the noroviruses, astrovirus is frequently acquired nosocomially. Two surveys in California found astrovirus and rotavirus at a similar frequency in the hospital setting. In both surveys, about half the astrovirus infections were thought to have been nosocomially acquired (Shastri et al. 1998; Rodriguez-Baez et al. 2002). The later survey (conducted 1998–2000) reported that 21 percent of hospitalized children (<6 years) had symptoms of gastroenteritis during their stay. Astrovirus was detected in 5.2 percent of the samples and 75 percent of these infections were symptomatic. Rotavirus accounted for only marginally more positive samples at 6.8 percent, suggesting that astrovirus has a similar incidence to rotavirus in this context. Rotavirus infections were, however, more severe and more likely to lead to dehydration (Rodriguez-Baez et al. 2002). Dennehy and colleagues (2001) obtained similar results in Australia; rotavirus was found to be the major cause of nosocomially acquired infection with astrovirus accounting for 16 percent. Community-acquired astrovirus was observed at a rate of 6.8 percent of samples. Once more rotavirus infection was clinically more severe. A survey in France examined the incidence of norovirus and astrovirus in hospitalized patients.

Infections were assigned as community or nosocomially acquired, depending on the delay between admission and development of illness. Where this period exceeded typical incubation times, infection had presumably been acquired in hospital. Approximately half the astrovirus infections identified and a third of the norovirus infections were found to be nosocomial (Traore et al. 2000). Foley and colleagues (2000) also found an approximately equal incidence of astrovirus and norovirus in presumed nosocomial infections in Ireland. Thus the majority of reports find that infection by all three agents can occur at about the same frequency in the hospital setting.

A further question to be considered is to what extent if any, animal strains of astrovirus might regularly cross-infect between species to reach humans. Sequence relatedness between feline and human astroviruses does suggest an evolutionary relationship, but this neither implies nor excludes more frequent traffic of viruses between these species. Certainly a recent large-scale survey of infectious intestinal disease in England and Wales found that recent contact with pets (cats and dogs) with diarrhea (but not with healthy animals) did carry an increased risk of developing intestinal disease. However, these cases tended to be associated with failure to detect a causative organism which was surprising (Food Standards Agency 2000). This in turn suggests that any zoonotically infecting agent might not be detected by the usual diagnostic methods used. Recent experimental data have shown that FAstV can infect human cells (CaCo-2) in culture, inducing cytopathic effect and leading to the release of progeny particles. These could not, however, be passaged further even when trypsin treated. This suggests that humans might be infectable with FAstV. Recombinant FAstV antigen was then used to modify an enzyme immunoassay (EIA) already developed for the type-specific detection of antibody to human astroviruses (Mitchell et al. 1999a). This test was then used to examine a panel of human sera previously characterized for antibody to HAstV types 1 and 6 (Kriston et al. 1996). The FAstV antigen was found to react with a panreactive non-neutralizing monoclonal antibody (Herrmann et al. 1988) but had no reactivity with rabbit sera raised to individual serotypes 1–7 of human astrovirus. This survey found that 7/262 (2.6 percent) of sera showed a specific reaction towards the feline virus antigen that did not correlate with cross-reacting seroconversion to any of the HAstV strains tested. Furthermore, samples from two different infants were negative for all seven human astroviruses tested, yet were positive for antibody recognizing the feline virus (W. D. Cubitt, unpublished observations). These data suggest that feline virus can infect humans, inducing seroconversion. However, it is not clear whether this is associated with any illness or if the infection is 'dead-end' and cannot be spread further between humans.

CLINICAL MANIFESTATIONS

Human and mammalian astroviruses

Human astroviruses are generally associated with fairly mild, self-limiting gastroenteritis in infants and young children. To some extent this view is likely to be an oversimplification (reviewed by Glass et al. 1996) Recent studies report that astrovirus is the second most common viral agent (after rotavirus) found in young children with diarrhea (Herrmann et al. 1991). However, astroviruses are also frequently identified in symptom-free individuals and it is clear that infection does not always result in clinical signs. The highest reported incidence was observed in rural Mayan infants. In this study 61 percent of a 3-year birth cohort showed astrovirus infection. Astrovirus was associated with 26 percent of all diarrheas observed and 17 percent of astrovirus positives were associated with diarrhea and a further 8 percent with other symptoms. In this study, astrovirus was found to be the major pathogen in that community, outstripping even rotavirus in incidence (Maldonado et al. 1998). However, findings from other surveys have revealed infection rates and symptom associations that were somewhat lower, e.g. 4.9 percent in Barcelona (Guix et al. 2002) and varied between 1.4 and 4.4 percent from 1995 to 1998 in Melbourne, Australia (Mustafa et al. 2000). However, it does not necessarily follow that illness is mild and astroviruses do result in hospitalization for severe diarrhea. In a study of such admissions in South Africa, rotavirus was found to be the most common viral cause at just under 30 percent but astroviruses were a highly significant second at 7.4 percent (D. Steele, personal communication). Even in the USA it has been estimated that astroviruses account for some 5 percent of all hospital admissions due to diarrhea (CDC 1990). There is currently no vaccine for astrovirus infection but an active program has targeted rotavirus for many years. Should such a vaccine enter general use, the relative significance of astrovirus-induced disease would rise.

The virus has an incubation period of 3–4 days that is followed by the appearance of diarrhea (typically two to six motions/day). This is the predominant clinical symptom of infection by these viruses and is accompanied by shedding of virus, which generally lasts for 2–3 days but may persist for up to 14 days (Kurtz and Lee 1987). Other reported symptoms include nausea and vomiting, headache, fever, and abdominal discomfort. A survey in London, UK found that 82 percent of children infected with astrovirus experienced diarrhea, 64 percent vomiting, 25 percent abdominal discomfort, and 18 percent mild dehydration (Nazer et al. 1982). A larger scale survey of infectious intestinal disease in the UK has analyzed symptoms reported by those infected with astroviruses: all those affected reported diarrhea as the

major symptom with 60 percent% of infected children described as incapacitated by the infection (Food Standards Agency 2000).

Further astrovirus-induced illness is not always mild in adults. An outbreak of severe gastroenteritis amongst French military recruits was associated with HAstV-3 (Belliot et al. 1997c) whilst the Food Standards Agency (2000) study in England and Wales found diarrhea as the major symptom in astrovirus-infected adults attending their GP surgeries; 65 percent described it as 'severe' and nearly 90 percent were 'incapacitated' by the illness. Abdominal pain and loss of appetite were also common in both children and adults but febrile effects (temperature, muscle ache, etc.) seemed more frequent in adults than in children and vomiting was more frequent in children (75 percent) than in adults (29 percent). It may well be that many adults remain at risk of symptomatic infection by higher serotypes of astrovirus to which cross-protective immunity resulting from infection with serotype 1 is poor (Koopmans et al. 1998).

Symptom severity has been investigated by means of volunteer studies: bacteria-free filtrates of astrovirus-containing stools have been introduced orally to adult volunteers; in general these have shown that the virus has low pathogenicity in healthy adults. Kurtz and colleagues (1979) inoculated eight volunteers with HAstV-1 and found that only one developed diarrheal illness (and shed large numbers of astrovirus particles) and a second volunteer reported mild symptoms (accompanied by a lower level of virus shedding). However, most of this panel would have been exposed previously to this virus serotype. A second study in the USA exposed 19 volunteers to serotype 5 virus; 47 percent of these persons had undetectable titers of astrovirus-specific serum antibodies when inoculated. One volunteer developed mild illness and nine had a serological response to the virus but did not report symptoms (Midthun et al. 1993). The conclusion from these studies is that astrovirus infection is usually relatively mild in otherwise healthy adults whilst the clinical pattern tells us that this cannot be universally true.

Astrovirus infections may be especially significant in vulnerable groups; outbreaks have also been reported in residential communities of elderly people (Gray et al. 1987; Lewis et al. 1989). In Marin County, California (Oshiro et al. 1981), 51 percent of the residents of a convalescent hospital (and 12 percent of the staff) developed symptoms. Most experienced minor illness lasting about 3 days and consisting only of diarrhea, although 13 percent of the patients also experienced fever. In the immunocompromised, virus shedding has been reported for several months following infection (Noel and Cubitt 1994) and the gastroenteritis caused may be severe (Coppo et al. 2000). Infections of hospitalized children undergoing immunosuppressive regimens may be prolonged and can prove difficult to eradicate from the unit (Cubitt et al. 1999). Prolonged infections may also be occurring in Bangladesh where a study found astrovirus was more frequently present in children <5 years who suffered from persistent diarrhea (15 percent) than in those with acute and short-lived illness (4 percent) (Unicomb et al. 1998). This suggests that in Bangladesh astrovirus may be an important contributor to the prolonged illness (defined as >14 days' duration) observed in 7 percent of diarrheal patients. In this setting, prolonged diarrhea is a serious condition and frequently results in death. However, it was not determined whether astrovirus was actually the cause of this persistent condition or simply secondary to it, nor was astrovirus linked to clinical severity. There have been few reports of any long-term consequences of astrovirus infection; however, short-term lactose intolerance and occasionally cows' milk intolerance lasting several months have been reported (Nazer et al. 1982; Kurtz and Lee 1987).

In other mammals, it is also generally the young of the species that show symptomatic infection and again diarrhea is the predominant symptom. These include lambs (Snodgrass and Gray 1977), calves (Woode and Bridger 1978; Woode et al. 1984), pigs (Shirai et al. 1985; Shimizu et al. 1990), mink (Englund et al. 2002), and cats (Hoshino et al. 1981; Harbour et al. 1987). The virus is clearly responsible for illness in the sheep and in cats it was severe enough to require hospitalization. However, in pigs and calves it appears relatively mild and the bulk of any symptoms observed may be due to coinfection by other agents.

Avian astroviruses

In birds, the range of symptoms produced by astrovirus is more diverse and generally more severe than in mammals. Astrovirus infection (DHV II) causes a rapidly fatal hepatitis in ducklings (Gough et al. 1984). Mortality rates can exceed 25 percent and have been reported up to 70 percent. Symptoms usually appear in 3–6-week-old birds. Examination revealed that the ducklings died of acute hepatitis with hepatocellular necrosis and generally, hyperplasia of the bile duct. Astrovirus-like particles were found by EM in the liver and feces and experimental transmission of the virus resulted in hepatitis and death within 2–4 days in five of 20 ducklings inoculated. Thus far the UK is the only reported country in which DHV II has struck and the origin of the virus remains unknown but is believed to result from contact with wild birds. The virus caused no symptoms in mature ducks, suggesting that adult birds might harbor the infection.

An avian astrovirus was first reported as a cause of gastroenteritis and mortality in turkey poults (6–11 days of age) in 1980 (McNulty et al. 1980). Since then there have been other reports of astrovirus outbreaks in turkeys resulting in enteritis and stunting of growth (Reynolds and Saif 1986). These features have been

linked to a temporary reduction in maltase activity in the small intestine, resulting in disaccharide maldigestion (Thouvenelle et al. 1995). More recently TAstV has been implicated as the causative agent of poult enteritis mortality syndrome (PEMS) in turkeys. This emerging disease is characterized by enteritis, growth depression, lymphoid atrophy, and, interestingly, immunosuppression (Koci et al. 2000a). The virus can be detected in the intestines, thymus, and bursa of infected birds. The virus can reduce macrophage viability and phagocytosis in vitro, thus leading to increased susceptibility of infected turkeys to secondary bacterial infections (Qureshi et al. 2001).

ANV infection of young chickens results in growth retardation of the birds by causing acute interstitial nephritis (Imada et al. 1979). The virus has been shown to be widely distributed in chickens, and turkeys may also be susceptible (Imada et al. 1980). Field strains of the virus show vastly different degrees of pathogenicity ranging from subclinical infections to death (Frazier et al. 1990; Shirai et al. 1991).

PATHOGENESIS

HAstV pathogenesis has not been extensively studied; duodenal biopsy taken during infection showed that the virus had infected the epithelial cells of the lower part of the intestinal villi (Phillips et al. 1982). In lambs experimentally infected with OAstV, lesions were seen throughout the small intestine, especially in the midgut and ileum (Snodgrass et al. 1979). The virus was found to replicate in the mature columnar epithelial cells situated in the apical two-thirds of the villi (virus was detected in the cytoplasm of these cells by EM). The damaged cells were replaced by immature crypt cells – resulting in villus atrophy and malabsorption typical of virus-induced enteric illness (Gray et al. 1980). By contrast, BAstV infection was confined to the specialized M cells that overlay Peyer's patches in the jejunum and ileum of the calves; these infected cells were then shed and replaced by immature crypt cells (Woode et al. 1984). It has been suggested that the limited number of susceptible cells in the bovine gut compared to that in the sheep could explain the lack of symptoms in experimentally infected calves (Kurtz and Lee 1987).

Little is known of immunity to astroviruses. Certainly antibody is developed early in life but Koopmans and colleagues (1998) suggest that little heterotypic protection may result and cross-neutralization activity was not detected in those serotypes where it was sought. HLA-restricted $CD4^+$ T cells specific for astrovirus have been identified in the duodenal mucosa of eight of eight normal (asymptomatic) individuals and these were thought to be of the Th1 phenotype. The fact that astrovirus-specific T cells can be isolated from normal small intestinal biopsies strongly suggests that the precursor frequency of virus-specific T cells in the mucosa is likely to be higher than in peripheral blood. This could suggest that the gut immune system frequently encounters these viruses, regularly reactivating any T cells to proliferate. The presence of these cells might then promote immunity to reinfection (Molberg et al. 1998). All the T-cell clones tested recognized a recombinant HAstV-1 capsid protein, demonstrating that the T-cell epitopes concerned must reside in that protein. The extent to which this cellular immunity is heterotypic has not been determined (O. Molberg, personal communication).

DETECTION AND DIAGNOSIS

Electron microscopy

Astroviruses were originally detected, and for many years could only be diagnosed by EM. This has almost certainly resulted in a reduced efficiency of diagnosis since the technique relies on specimens that contain high levels of virus particles exhibiting good morphological preservation. Astroviruses may be shed in large numbers during infection (up to 10^{10} particles/g feces; Kurtz and Lee 1987), but this is by no means always the case; particles may be hard to find and their preservation may not be good. It has been found that the virions are unstable if pelleted from cesium chloride gradients and are better purified using potassium tartrate (Ashley and Caul 1982). Astrovirus morphology may itself be inherently variable (see section on Morphology, above). Although a typical astrovirus can be safely identified as such, specimens lacking these features cannot readily be discounted. If stars are not visible, a featureless particle would be observed and these can easily be mistaken for parvovirus-like agents. Reanalysis by culture and blotting of a panel of EM-identified parvoviruses revealed the majority to be astrovirus (Willcocks et al. 1991).

Oliver and Phillips (1988) carried out retrospective analyses of samples that had originally been classified on the basis of their appearance in the electron microscope and showed that several samples (14 of 53 re-examined) originally identified as 'small round' or 'parvovirus-like' viruses were in fact astroviruses. This particular confusion is significant since some laboratories have reported the small round virus (parvovirus-like) agents as the second most frequently identified virus (Lew et al. 1990). Alternatively, particles may be larger than expected, (possibly coated in antibody) and the margins of the particle might not be smooth. Indeed, Marin County virus was initially identified as a calicivirus due to these affects (Oshiro et al. 1981). These variations in structural parameters have undoubtedly clouded attempts to assess the significance of astroviruses in disease. The recent large-scale survey of infectious intestinal disease in the UK has identified astroviruses by EM, using ELISA methods only to confirm those found as positive by this

means. Presumptive 'parvoviruses' have not been further examined. This is likely to underestimate the occurrence of astrovirus and this survey has yielded incidence figures similar to other EM-based surveys rather than the higher values usually associated with ELISA methods. One major advantage of EM, however, is that it is a 'catch-all' diagnostic tool, allowing any other potential pathogens in the specimen to also be detected. A survey in London, UK found that of 28 infants infected with astrovirus 16 were also infected with another enteric pathogen (Nazer et al. 1982). In patients shedding fewer particles, immune electron microscopy has proved a valuable tool (Berthiaume et al. 1981).

Cell culture

It was initially difficult to establish cell culture methods for astroviruses, and to date only the porcine and human strains can be cultured in vitro. Both were originally propagated in renal cells of the host species (Lee and Kurtz 1981; Shimizu et al. 1990). The viruses were only able to grow with the addition of trypsin (at 5–10 μg/ml) to the culture medium. In the absence of trypsin, infection could occur but did not give rise to infectious progeny (Lee and Kurtz 1981). This trypsin level caused disruption of the cell monolayer and no cytopathic effect was apparent. However, Hudson and colleagues (1989) did succeed in developing both a plaque assay for three of the serotypes (again with the addition of trypsin to the overlay), and a virus neutralization assay. PAstV required the addition of 0.5 μg trypsin to grow and limited cytopathic effect was visible in the porcine embryonic kidney cells (Shimizu et al. 1990).

Since these experiments, three human cell lines have been identified that are able to support the replication of HAstV directly from clinical samples. Two of these (CaCo-2 and T84) are gut-cell lines and one (PLC/PRF/5) is derived from a hepatoma.

Willcocks and colleagues (1990) found that a human colonic carcinoma cell line (CaCo-2 cells) could be infected with HAstV. Trypsin was required (at 5 μg/ml) for productive growth and at this concentration these cell monolayers remained relatively intact. Cytopathic effect became apparent from 2 days post-infection. These cells also supported the partial replication of FAstV in that infections could be established using viruses from feline diarrheal feces; mRNA and protein synthesis occurred and progeny particles were released. However these were found to be non-infectious and infectivity could not be rescued by addition of trypsin.

Taylor and colleagues (1997) found that a human hepatoma cell line (PLC/PRF/5) was also able to support the replication of human astroviruses directly from clinical samples. Trypsin was required (10 μg/ml) and the disruption caused by this to the cell monolayers did not permit detection of any cytopathic effect. Virus growth was monitored by EM or indirect immunofluorescence. In addition to these cells, the Oxford adapted astrovirus strains have a wider host cell range (Brinker et al. 2000).

Although cell culture is essential for isolating viruses from clinical samples, it is not generally the method of choice for diagnostic purposes because it is labor intensive, slow, expensive, and less sensitive than immunologically based or PCR-based assays. It has, however, been used successfully to enhance the detection level of RT-PCR for samples where virus particles should be highly dilute, e.g. drinking water. Concentrated samples were propagated in CaCo-2 cells before analysis by RT-PCR (Abad et al. 1997). A similar approach has been used in environmental water samples (where propagation in PLC/PRF/5 cells was employed; Marx et al. 1995) or in sludge biosolids (where integrated cell culture/RT-PCR was coupled with nested PCR; Chapron et al. 2000).

Enzyme immunoassays

Herrmann and co-workers (1988) developed an enzyme immunoassay (EIA) for astrovirus, using a monoclonal antibody to the group antigen to capture virus; this detected all astroviruses grown in cell culture. These workers later modified the test to detect astroviruses in stool samples (Herrmann et al. 1990). Compared with immune electron microscopy, this assay has as high a sensitivity (91 percent) and specificity (98 percent). Moe and colleagues (1991) developed a modified version of the assay using a biotinylated detector antibody. These assays have been particularly useful in epidemiologic studies, where large numbers of samples need to be assayed (Herrmann et al. 1991; Lew et al. 1991; Moe et al. 1991; Cruz et al. 1992; Walter et al. 2001b). A latex agglutination test specific for HAstV-1 has also been reported for this application (Kohno et al. 2000).

Modifications to these tests using recombinant antigen have also allowed the development of ELISA or immune fluorescence-based methods to detect serum antibody and thus determine the prevalence of antibodies to astroviruses in various communities. When used in this way, baculovirus-expressed antigen reacts in a serotype-specific manner, allowing antibody to each serotype to be assessed independently (Kriston et al. 1996; Mitchell et al. 1999a).

Molecular methods

A dot-blot hybridization procedure for detecting astroviruses in fecal samples has been described (Willcocks et al. 1991) but has only been used in a small-scale study (Silcock et al. 1993). A liquid hybridization assay was successfully tested on 26 wild strains of the virus (Belliot et al. 2001). As sequence data has accumulated a number of RT-PCR tests have been developed (Monroe et al. 1993; Jonassen et al. 1995; Noel et al. 1995; Yue

and Ushijima 1996; Sakamoto et al. 2000; Traore et al. 2000). These have facilitated the rapid diagnosis of human astrovirus outbreaks (Cubitt et al. 1999). Oligonucleotide primers designed to match conserved sequences can detect all serotypes. Primer pairs have been reported targeting the 3′ end of the genome (Monroe et al. 1993; Jonassen et al. 1995), the RNA-dependent RNA polymerase gene (Belliot et al. 1997b) and from the 5′ end of the capsid gene (Sakon et al. 2000). RT-PCR has also been used for genotyping of human astroviruses by sequencing of a 348-bp amplimer from the capsid gene (Noel et al. 1995). However, this method has epidemiologic rather than diagnostic applicability. An RT-PCR has also been reported for the detection of TAstV in PEMS-affected commercial turkey flocks (Koci et al. 2000b).

The technique has also been useful in confirming results with specimens that gave ambiguous results in other tests (Grohmann et al. 1993) and has been able to provide more detail on outbreaks. Mitchell and colleagues (1995) used EIA and RT-PCR to screen fecal specimens in an outbreak of gastroenteritis in a child-care center. EIA found that stools from 75 percent of the infants, 50 percent of the toddlers, and 20 percent of the children were positive, whilst using RT-PCR increased the numbers to 100, 79, and 90 percent, respectively. This changed the interpretation of the outbreak; the virus had not selectively infected some of the children but had in fact infected almost all of them. The number of days of virus shedding was also found to be longer using this more sensitive method and increased from 1 to 9 days (as detected by EIA) to up to 35 days (as detected by PCR).

CONCLUSIONS

Astroviruses are becoming increasingly appreciated as agents of human disease to which we are regularly exposed from each other and the environment, and possibly from animals. Infections within institutional settings, often affecting those at particular risk, pose a particular problem. The significance of these agents as the second most frequent cause of gastroenteritis in children worldwide, and their possible association with prolonged illness in the third world, demands attention. Rotavirus remains the single most significant cause of childhood diarrhea and rightly receives the attention required to develop vaccines. However, control of rotavirus infection does not control gastroenteritis; vaccinees would remain susceptible to astrovirus infection and this could lead to a perceived lack of vaccine efficacy that could restrict vaccine uptake.

Human enteric RNA viruses: Noroviruses and Sapoviruses

IAN N. CLARKE AND PAUL R. LAMBDEN

Historical perspectives	1	Animal enteric caliciviruses	16
Noroviruses	2	References	17
Sapoviruses	13		

HISTORICAL PERSPECTIVES

Diarrheal disease in humans, clinically distinct from bacterial gastroenteritis, was first reported in the southern USA. It was originally described as 'hyperemesis hiemis' or winter vomiting disease (Zahorsky 1929), a term that reflects its seasonality. The illness occurred in widespread epidemics with a high secondary attack rate, and was documented as a short, self-limiting episode of vomiting with some diarrhea. Later, this syndrome was also recognized by clinicians in the UK (Bradley 1943; Gray 1939; Miller and Raven 1936). Its distinction from bacterial gastroenteritis was confirmed by investigations of institutional outbreaks in which stool cultures were consistently negative for pathogenic bacteria.

Between the 1940s and the early 1970s, a variety of synonymous terms were used for this syndrome, including nonbacterial gastroenteritis, epidemic gastroenteritis, acute infectious nonbacterial gastroenteritis, and winter vomiting disease. The transmissibility of an agent by oral inoculation of human volunteers with a fecal filtrate was repeatedly demonstrated (Adler and Zickl 1969; Clarke et al. 1972; Dolin et al. 1971; Gordon et al. 1947; Jordan et al. 1953; Reimann et al. 1945). This approach established the possibility of a viral etiology, and although the natural history of this transmissible agent was comprehensively described, all attempts to isolate a bacterial pathogen or a viral agent failed.

An outbreak of epidemic gastroenteritis in a primary school in Norwalk, Ohio, USA led to confirmation of the viral etiology of winter vomiting disease (Kapikian et al. 1972). Fecal filtrates from affected children were fed to volunteers, whose stools were examined by immunoelectron microscopy. A previously undescribed virus-like particle, 27 nm in diameter, was detected and subsequently named Norwalk virus. Further studies in volunteers established Norwalk virus as the agent responsible for the original outbreak. Seroconversions or rising IgG titers, as well as virus excretion, were demonstrated in infected volunteers, and the histopathology of jejunal biopsies from those with acute disease gave new insights into the cell tropism of Norwalk virus in the small intestine (Agus et al. 1973; Schreiber et al. 1973). Further volunteer studies by American workers identified viruses morphologically similar to the Norwalk virus in two outbreaks of nonbacterial gastroenteritis. These viruses were termed Montgomery County and Hawaii, respectively, after the locations of the outbreaks. This mode of nomenclature became common (Caul 1988) and laboratories continue to name strains after the location of isolation.

Soon after the discovery of the Norwalk virus, morphologically indistinguishable viruses from clinically similar outbreaks were reported. The agents responsible for these virologically characterized outbreaks were termed Hawaii (Thornhill et al. 1977; Wyatt et al. 1974), Snow Mountain (Dolin et al. 1982; Morens et al. 1979) and Taunton (Caul et al. 1979; Pether and Caul 1983).

Volunteer studies were central to the understanding of the transmissibility, pathogenesis, and immunobiology

of the Norwalk and Hawaii viruses (Parrino et al. 1977; Schreiber et al. 1973; 1974; Wyatt et al. 1974) and established a previously undescribed and poorly characterized group of related viruses as an important cause of epidemic gastroenteritis. The Norwalk-like viruses cause acute, explosive diarrhea, vomiting, or both, and are highly infective, with rapid secondary spread. Large outbreaks have been described in semiclosed communities throughout the world as a result of person-to-person spread (Caul 1988; Christensen 1989; Kaplan et al. 1982; Pether and Caul 1983). Point-source outbreaks resulting from the ingestion of sewage-contaminated water, contaminated shellfish or food (Morens et al. 1979; Murphy et al. 1982) emphasize the great public health importance of these viruses. There are major problems in controlling such outbreaks, and the economic implications, including those applicable to the food and shellfish industries, are being increasingly recognized.

The widespread application of electron microscopy (EM) to the examination of diarrheal stool samples resulted in major advances in our understanding of the etiology of nonbacterial gastroenteritis. Rotaviruses were rapidly identified as major pathogens in endemic infantile gastroenteritis, and other viruses, including 'fastidious' adenoviruses, were added to the list of enteric 'diarrhea' viruses. In addition to these distinctive viruses there were many reports of an apparently wide range of small-round viruses (SRV) approximately 30 nm in diameter. In many studies SRVs were identified by immunoelectron microscopy (IEM), which masks surface morphology, and often resulted in a confusing picture of the etiology of nonbacterial gastroenteritis. Other SRVs were identified from their classic surface structure, and detailed descriptions of the morphology of the newly described astroviruses and 'classic' caliciviruses were published (Madeley 1979).

In 1982 an 'interim classification scheme' was presented (Caul and Appleton 1982) as an to aid national surveillance within the UK and to establish which SRVs were causally related to viral gastroenteritis. The authors concluded that the causative agents of diarrheal disease were the SRVs that possessed surface morphology to which descriptive terms could be applied. These viruses included the previously described astroviruses, 'classic' caliciviruses, and a third group of viruses that shared the features of an amorphous surface structure and 'ragged'-edged virions. This third group was represented by the prototype Norwalk virus, and within the interim scheme were termed small-round structured viruses (SRSV). A prerequisite for classification under this scheme was that all viruses were examined in the absence of antibody to ensure that any surface structure would not be obscured. SRSVs emerged as the most important cause of epidemic nonbacterial gastroenteritis worldwide, with viruses of this group causing similar illnesses.

This morphological classification scheme recognized fundamental differences between astroviruses, the classic caliciviruses, and SRSVs, and was supported by epidemiological and immunological distinctions (Blacklow and Greenberg 1991; Caul 1988). The molecular characterization of these three different viruses showed that they contained positive-sense single-stranded RNA genomes. The genome structure of astroviruses, however, is very different from that of the SRSVs and 'classic' caliciviruses, and so the astroviruses have been assigned to a separate virus family and are discussed in Human enteric RNA viruses: Astroviruses. SRSVs and the 'classic' caliciviruses both belong to two separate genera within the *Caliciviridae*, which from 1998 to 2002 were temporarily called Norwalk-like viruses (NLV) and Sapporo-like viruses (SLV), respectively. The ICTV has now settled on a new nomenclature for these genera, namely Noroviruses and Sapoviruses, reflecting the place of discovery of each of the prototypes. The clinical, epidemiological and pathological aspects of Noroviruses and Sapoviruses are summarized (Table 1).

On the basis of sequence analysis and genome organization, human enteric caliciviruses have been assigned to two separate genera within the *Caliciviridae* (Jiang et al. 1993; Lambden et al. 1993; Dingle et al. 1995). The SRSVs or Norwalk-like viruses belong to the *Norovirus* genus and the Sapporo-like or 'classic' caliciviruses are members of the *Sapovirus* genus. Two other genera are included in the family and contain viruses pathogenic for animals. The *Vesivirus* genus includes *Feline calicivirus* and *Vesicular exanthema of swine virus*. The fourth genus, *Lagovirus*, is represented by the *Rabbit hemorrhagic disease virus* (RHDV) and the closely related *European brown hare syndrome virus* (EBHSV).

NOROVIRUSES

Classification and morphology

The prototypic Norwalk virus was originally described as non-enveloped, round, 27-nm particles with a 'ragged' outer edge but lacking a definite surface structure (Kapikian et al. 1972). The low titer of virions found in stool samples, together with their small size and amorphous structure, has made them difficult to detect by direct EM. Many other Noroviruses have been described and have in common a buoyant density of 1.33–1.41 g/cm^3, an inability to propagate in vitro, and an RNA genome of positive polarity (Greenberg and Matsui 1992).

Characteristically, Noroviruses possess a single capsid protein (Greenberg et al. 1981), but lack of a cell-culture system has restricted the production of capsid antigen to recombinant heterologous expression systems. Capsid proteins expressed in insect cells using

Table 1 *The clinical, epidemiological and pathological aspects of Noroviruses and Sapoviruses*

Appearance	Genome structure	Clinical features	Examples
Noroviruses			
Feathery, ragged outline No distinctive surface structure Some preparations resemble classic calicivirus No cell-culture system	ssRNA, +ve polarity, polyadenylated, ca. 7.7 kb group I and 7.5 kb group II ORF1 nonstructural polyprotein ORF2 capsid ORF3 small basic protein Possible subgenomic RNA	Winter vomiting disease Epidemic nausea vomiting and diarrhea Acquisition of antibodies is gradual, vomiters are more likely to seroconvert Peak illness in adults No immunity Clinical features identical for group I and group II viruses	**Group I:** *Norwalk virus*: (school outbreak, USA 1969) Southampton virus (family outbreak, UK 1991) **Group II:** Hawaii virus: (family outbreak, USA 1972) Lordsdale virus (hospital outbreak, UK 1993)
Sapoviruses Distinctive cup-shaped surface depressions, giving classic 'Star of David' morphology No cell-culture system	ssRNA, +ve polarity, polyadenylated, ca. 7.3 kb ORF1 nonstructural polyprotein contiguous with and fused to capsid gene ORF2 small basic protein Subgenomic RNA and VPg present in animal viru	No seasonal variance Predominantly pediatric illness Antibodies acquired at young age Diarrheal illness usually mild	**Group I:** *Sapporo virus*: outbreak in an orphanage Sapporo and Japan, 1982 Manchester virus: sporadic case of acute vomiting and diarrhea in a 6-month-old child (1993) **Group II:** Bristol virus: sporadic case 15-month -old child (1998) London virus: 8-month-old infant hospitalized for diarrhea and vomiting (1992)

baculovirus vectors spontaneously assemble to form virus-like particles and are released into the cell culture supernatant (Dingle et al. 1995; Jiang et al. 1992; Jiang et al. 1995b). These virus-like particles are larger in diameter and have the appearance of empty virions (Figure 1).

Cryo-electron microscopy and computer image processing techniques have determined the empty virion structure to a resolution of 2.2 nm (Rothnagel et al. 1994) (Figure 2). The empty capsids are composed of 90 dimers of the capsid structural protein and are 38 nm in diameter, with T = 3 icosahedral symmetry. Archlike capsomers formed from dimers of the capsid structural protein and deep depressions at the five- and three-fold axes are distinctive features. Each virus-like particle has 32 surface hollows surrounded by the protruding arches. Twelve hollows are at the icosahedral fivefold axis and have a small hump at the center. The other 20 hollows at the three-fold positions seem to be flat. This distinctive molecular architecture has also been described for a primate calicivirus (Prasad et al. 1994).

The structure of recombinant Norwalk virus capsids at near-atomic resolution has been determined by X-ray crystallography (Prasad et al. 1999, 2000). The structure of the capsid protein is organized into two domains joined by a flexible hinge (Figure 3). The inner shell (S) domain is composed of the N-terminal 225 residues and is involved in the formation of the icosahedral capsid shell. The shell domain also shows the classic eight-stranded β barrel structure typical of many viral capsid proteins. The protruding (P) domain forms prominent structures extending from the surface of the shell, and is formed from the C-terminal half of the protein. The P domain is further organized into two subdomains (P1 and P2), and it has been suggested that these structures may be involved in binding to cellular receptors and may also be the determinants of strain specificity (Prasad et al. 1999). Mutational analysis of the critical residues involved in VLP formation (Bertolotti-Ciarlet et al. 2002) has shown that complete removal of the P domain resulted in the formation of smooth particles with a diameter slightly less than that of the complete rNV VLPs. These studies demonstrated that the shell domain alone of the capsid protein was able to initiate spontaneous assembly into particles, but the P domain was required for particle stability.

Genome organization

Since the first reports of the molecular cloning of the Norwalk virus genome in 1990, rapid progress has been made in the genome analysis of Noroviruses. Virus purified from feces of volunteers infected with Norwalk virus was used to generate a library of cDNA clones representing most of the viral genome. Authentic clones were identified by hybridization to post- but not preinfection stool nucleic acid. Sequence information indicated that the Norwalk virus genome is single-stranded positive-sense RNA of about 7.5 kb and polyadenylated at the 3′ terminus (Jiang et al. 1990). In one of the viral clones a motif characteristic of viral RNA-dependent RNA polymerases was identified. Matsui and colleagues (Matsui et al. 1991) then cloned a region of the Norwalk virus genome that was immunoreactive when expressed in recombinant λ phage. Following these early studies a number of complete genome sequences of human Noroviruses (Dingle et al. 1995; Green et al. 2002; Hardy and Estes 1996; Jiang et al. 1993; Katayama et al. 2002; Lambden et al. 1993; Lambden et al. 1995; Pletneva et al. 2001; Schreier et al. 2000; Seah et al. 1999; Someya et al. 2000) have been determined, together with numerous partial sequences covering the RNA polymerase and capsid regions in the 3′ half of the genome.

Phylogenetic analyses of the RNA polymerase and capsid regions of the genome indicate that human Noroviruses are divided into two genetic groups (Ando et al. 1994; Cubitt et al. 1994; Green et al. 1994; Wang et al. 1994). The genome of group I viruses is slightly larger (7.7 kb) than the group II genome (7.5 kb), although computer analyses reveal that the reading frame usage of these two genetic groups is very similar. The genomes of both group I and group II Noroviruses (Figure 4) are characterized by a large 5′ open reading frame (ORF) encoding a nonstructural polyprotein of approximately 1 700 amino acids, followed by a smaller ORF encoding the capsid structural protein.

The N and C termini, together with the hinge region between the shell and protruding domains, are indicated. (Image courtesy of Dr B.V.V. Prasad, Baylor College of Medicine, Houston TX, USA.)*

At the 3′ end of the genome is a small ORF, predicted by computer analysis to encode a basic protein. This genome organization clearly distinguishes Noroviruses from other positive-strand RNA viruses, such as the picornaviruses.

The smaller size of the group II *Norovirus* genome is attributable to its smaller ORF1. The nucleotide (nt) sequence in the 5′ region of ORF1 shows significant diversity between the two genetic groups, although distal to this variable region both groups show the characteristic motifs of the NTPase, cysteine protease, and RNA polymerase in the same relative genomic positions. Sequence diversity at the 5′ end of the genome may reflect fundamental differences between the two groups of viruses in terms of secondary structures or regulatory signals. The first 110 nucleotides of the Norwalk virus genome have been shown to form stable complexes with several cellular proteins from HeLa and CaCo cell extracts (Gutierrez-Escolano et al. 2000). The proteins La, PCBP-2, PTB, and hnRNPL, which are required for translation in poliovirus and hepatitis C virus, may also be essential for translation of caliciviral RNA.

The capsid coding region in the *Norovirus* genome is similar to the arrangement in feline calicivirus (FCV), in which ORF2 is frame-shifted relative to ORF1 so that the N terminus of the capsid protein overlaps the C terminus of the putative RNA-dependent RNA polymerase. However, the extent of reading frame overlap differs between the two genetic groups of Noroviruses, being 17 nt in group I and 20 nt in group II. The small 3′ ORF is also in a different reading frame from the capsid-encoding ORF2. The first residue of the initiator codon of ORF3 overlaps the last base of the terminator codon of the capsid gene. A characteristic feature of the animal caliciviruses is the production of a 3′ co-terminal polyadenylated subgenomic RNA coding for the capsid and small 3′ ORF. This subgenomic RNA is thought to provide an additional message for the production of capsid protein, and in the case of RHDV this additional RNA is packaged into mature virions (Meyers et al. 1991). It is not yet clear whether Noroviruses produce a subgenomic message, although detection of RNA of over 2 kb by Northern blot analysis of total stool RNA from a volunteer infected with Norwalk virus suggested that this virus also produces a subgenomic RNA (Jiang et al. 1993). A characteristic feature of the animal calicivirus genomic and subgenomic RNAs is that the 5′ termini are highly conserved (Lambden and Clarke 1995). The 5′ terminal sequence of ORF1 is repeated around the 5′ terminal region of ORF2, suggesting that human enteric caliciviruses, like their animal counterparts, also produce a subgenomic RNA. The 5′ genomic and subgenomic termini of both groups I and II Noroviruses begin with the sequence GU, and by analogy with the animal caliciviruses this terminal sequence is linked to the VPg

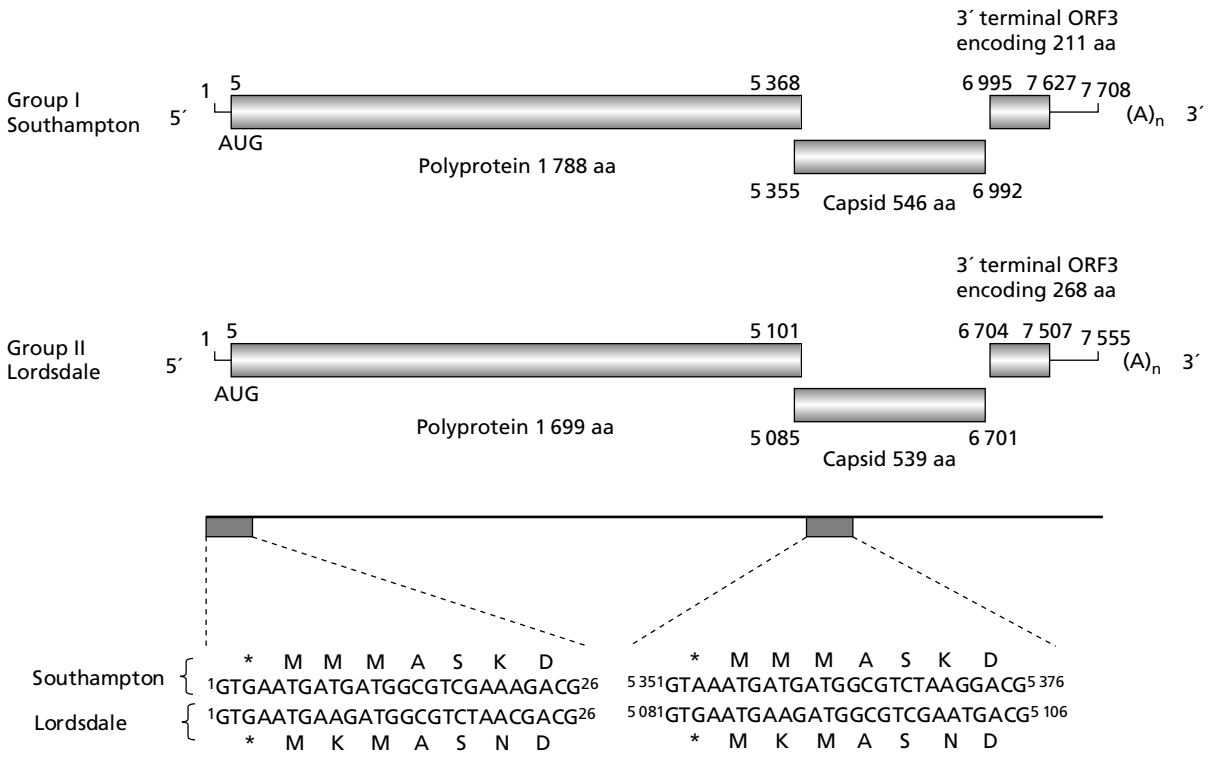

Figure 4 *Comparison of the genome structures of groups I and II Noroviruses. Shaded boxes represent computer-predicted open reading frames. Translation products and their sizes are indicated on the open reading frames. protein. The conserved GU residues at the 5′ genomic termini appears to be a common feature of the *Caliciviridae*. The amino acid involved in the linkage between VPg and the RHDV genome has been identified as Tyr-21 (Machin et al. 2001).

Viral proteins

Highly purified Norwalk virus recovered from CsCl equilibrium density gradients contains a single protein of 59 kDa (Greenberg et al. 1981). The single capsid protein was identified by radioimmunoprecipitation of purified virions with acute and convalescent sera from infected volunteers. Similar studies with the antigenically distinct Snow Mountain agent revealed a major structural polypeptide of 62 kDa (Madore et al. 1986). In addition to the 59 kDa capsid protein of Norwalk virus, a soluble protein with a molecular weight of 30 kDa was also detected in the supernatant of fecal suspensions. It has been estimated that up to 50 percent of the excreted antigen is present as soluble protein (Jiang et al. 1992). Until recently the source of the soluble protein remained uncertain, and was suggested to be an immunogenic nonstructural protein or a cleavage product derived from the capsid protein. However, analysis of virus-like particles expressed from insect cells infected with recombinant baculovirus demonstrated that the 30 kDa protein is a specific cleavage product of the viral capsid (Hardy et al. 1995). Recombinant Norwalk virus treated with trypsin released a 32 kDa protein, and analysis of the N-terminal sequence of this product revealed that a trypsin-specific cleavage occurred at amino acid residue 227. The 30 kDa soluble protein reacted with rabbit polyclonal antisera raised against recombinant Norwalk virus capsids, and analysis of the N-terminal sequence of the approximately 30 kDa soluble protein showed it to be identical to the 32 kDa trypsin cleavage product. In addition, it was shown that the 32 kDa proteolytic cleavage product is derived from soluble capsid protein and not intact assembled virions. These data suggest that the Norwalk virus capsid undergoes proteolytic cleavage during the course of infection. Japanese isolates antigenically related to the Hawaii virus also demonstrated immunoreactive structural proteins of 63 and 30 kDa by Western blot analysis (Hayashi et al. 1989; Oishi et al. 1992).

Several groups have described capsid gene sequences from a number of different *Norovirus* isolates that encode proteins with predicted molecular weights of approximately 60 kDa. Computer alignments of the capsid sequence data support the division of Noroviruses

into two major genetic groups. The capsid proteins have approximately 68 percent amino acid sequence identity within a genetic group and 40 percent between groups. However, the *Norovirus* capsids show only limited homology with the corresponding proteins in members of the other genera. A dendrogram showing the phylogenetic relatedness of caliciviruses is shown in Figure 5. The prototype Norwalk virus and the antigenically distinct Southampton virus are both members of genetic group I, together with the Desert Shield virus. A UK isolate, Lordsdale virus, has been assigned to genetic group II, along with Snow Mountain agent, Hawaii virus, Toronto virus, and Mexico virus.

The first major ORF encodes a polyprotein that is presumably processed by a proteolytic cascade analogous to that of picornaviruses. Computer analysis of the ORF1 sequence data has identified conserved amino acid motifs typical of the picornaviral 2C NTPase, 3C protease, and RNA-dependent RNA polymerase. NTPase activity has been demonstrated in recombinant p41of Southampton virus expressed as an *Escherichia coli* fusion protein (Pfister and Wimmer 2001). Sequence comparisons of group I and II Noroviruses reveal, apart from the short conserved sequence motifs, extreme sequence diversity at the 5′ proximal regions of the genomes. In RHDV the genomic and subgenomic RNAs are linked at their 5′ termini to a small protein analogous to picornaviral VPg, although the caliciviral protein (approximately 15 kDa) is considerably larger than the picornaviral equivalent (22 amino acids). The presence of a VPg-like protein, encoded by ORF1 in Noroviruses, is strongly inferred by analogy with the animal caliciviruses.

Although no specific biological function has been assigned to the translation product of ORF3 it has been reported that this protein is present in mature virions (Glass et al. 2000). A role for ORF3 protein as a minor capsid protein has also been reported in vesiviruses (FCV) (Sosnovtsev and Green 2000) and lagoviruses (RHDV) (Wirblich et al. 1996). The ORF3 translation product shows considerable sequence variation both within and between genera, which is surprising if the predicted protein product has the same functional role in all caliciviruses. It has been proposed that this basic protein may play a role in RNA packaging and assembly of the mature virion.

Polyprotein processing

In common with picornaviruses, caliciviral proteins are synthesized as a large polyprotein precursor which is subsequently processed in a proteolytic cascade by the viral 3C-like protease. In vitro transcription and translation of genomic clones does not appear to generate the intact polyprotein, suggesting that proteolytic processing probably occurs cotranslationally. Using in vitro mutagenesis and expression of the active protease in *E. coli*, five cleavage sites have been identified in Southampton *Norovirus* (Figure 6) (Liu et al. 1996; Liu et al. 1999b). Two of the cleavages in Southampton virus are at QG dipeptides and are responsible for the release of the p48 N-terminal protein and p41 NTPase from the polyprotein. Three further cleavages at EA and EG dipeptides generate the p22 (3A), p16 (VPg), p19 (3C protease), and p57 (RNA-dependent RNA polymerase). The preference for a glutamate residue at the P1 position of the cleavage dipeptide is also evident in FCV (Sosnovtsev et al. 1998, 2002) and RHDV (Wirblich et al. 1995; Meyers et al. 2000). The amino acid at the P1′ position of the cleavage dipeptide is more variable, but there appears to be a marked preference for glycine residues. The P4 position N terminus of the scissile bond also appears to be important in efficient processing (Hardy et al. 2002).

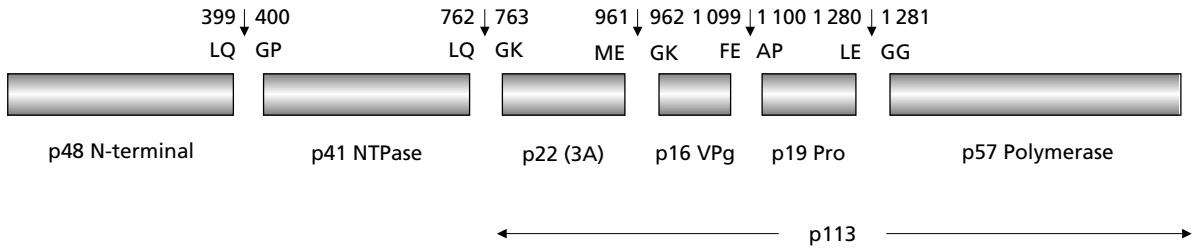

Figure 6 *Proteolytic cleavage map of the Southampton virus polyprotein encoded by ORF1. The shaded boxes represent the mature cleavage products of the nonstructural polyprotein. Cleavage sites are indicated between the boxes, and the amino acid coordinates at the P1/P1′ cleavage dipeptide are given each side of the arrows. The calculated molecular masses and functions of the cleavage products are indicated below the boxes. The large primary cleavage product (p113) observed in in vitro translation reactions extends from amino acid 763 to the carboxy terminus of the 3D polymerase and is indicated by the arrow below the cleavage map.*

Antigenic variation

Several approaches have been used in an attempt to evaluate antigenic relationships between the Noroviruses. Using human volunteers, cross-challenge studies have demonstrated that Norwalk and Hawaii viruses are antigenically distinct (Kapikian 1994), and further volunteer studies with the Montgomery County agent identified a one-way cross-protection with Hawaii virus. There was short-term homologous immunity after challenge of humans with all three viruses (Dolin et al. 1972; Wyatt et al. 1974).

The antigenic relatedness of Norwalk, Hawaii, and Snow Mountain viruses was also studied by testing serological responses in volunteers. Using an enzyme immunoassay (EIA) variable degrees of antigenic relatedness were observed, with a two-way cross-reaction between Snow Mountain and Hawaii virus and a one-way cross-reaction between Norwalk and Snow Mountain viruses (Madore et al. 1990). These results may reflect heterologous responses and contrast with the greater specificity of IEM or solid-phase immunoelectron microscopy (SPIEM), which is based on the use of intact virions (from fecal specimens) and convalescent sera.

Four antigenic types of *Norovirus* were originally described in the UK, identified by IEM or SPIEM (Lambden et al. 1993; Lewis 1991; Lewis 1990), six in the USA (Lewis et al. 1995) and nine in Japan (Okada et al. 1990). However, all the above methods suffered from the same technical drawbacks of poorly defined and limited reagents, which meant it was not possible to compare the differently defined antigenic 'types'. Although these were useful methods in the early days of research they have largely been replaced by modern molecular methods.

A definitive approach for serotyping Noroviruses based on neutralization is not possible because there is no cell-culture system. The ability to express the capsid protein in insect cells where it assembles to form virus-like particles, first demonstrated for Norwalk virus (Jiang et al. 1992), was a significant advance that has provided a renewable source of capsid antigen for many different strains. Apart from their use in structural studies, purified VLPs have been used to raise polyclonal and monoclonal antisera for the development of new diagnostic reagents. Several antigen capture EIAs have been developed using polyclonal antisera to VLPs from different animal species. Evaluation of these assays has shown that they are highly *Norovirus* strain specific; thus EIAs for Norwalk or Mexico virus will detect only homologous antigens (Graham et al. 1994; Jiang et al. 1995a). Phylogenetic analysis of capsid sequences suggests that the clustering of strains that show high levels of sequence conservation is also reflected by immunological relationships defined by EIA. However, some caution must be exercised in interpreting the meaning of these observations, as immunological relationships defined by EIA may still mean that viruses are not serotypically related as defined by virus neutralization.

Clinical manifestations

Detailed information on the clinical, immunological, and pathological aspects of Noroviruses have been established from investigations on volunteers (Kapikian 1994), in whom infections by Norwalk virus, Hawaii agent, Montgomery County agent, and the Snow Mountain agent are clinically indistinguishable (Morens et al. 1979; Wyatt et al. 1974). Following transmission by the fecal–oral route, volunteer and epidemiological studies have established an incubation period of approximately 24 h (Kapikian 1994), with a dose-dependent range of 18–48 h (Blacklow and Herrmann 1988). Symptoms are sudden in onset and are accompanied by nausea and vomiting, which can be projectile and severe. Low-grade fever and diarrhea usually occur, the latter being relatively mild. In contrast to bacterial gastroenteritis, diarrheal stools do not contain blood, mucus, or white cells. Other symptoms include mild abdominal pain or cramps, malaise, and headaches. Vomiting may arise from a decrease in gastric motility (Meeroff et al. 1980), giving rise to a reflux action into the stomach. Respiratory

involvement has not been observed, and nasopharyngeal washings from an acutely ill volunteer did not induce disease on passage to other volunteers (Dolin et al. 1972).

In general, *Norovirus* infections are self-limiting and affected patients rarely need to be hospitalized. There have, however, been occasional reports of severe dehydration that required the administration of intravenous fluids. Deaths associated with *Norovirus* infections are exceptionally rare and have not been directly attributed to this group of viruses (Kaplan et al. 1982).

Pathogenesis

Volunteer studies show that as few as 10–100 infectious particles may be needed to initiate infection. Replication is considered to occur in the mucosal epithelium of the small intestine, although direct evidence is lacking. Light microscopy of jejunal biopsies from volunteers infected with Norwalk virus showed partial flattening and broadening of the villi, with disorganization of the mucosal epithelium (Agus et al. 1973; Schreiber et al. 1973). The lamina propria was infiltrated with mononuclear cells and vacuolization of mucosal epithelium was noted. Crypt cell hyperplasia was common, and, at the ultrastructural level, mucosal epithelial cells showed dilatation of the rough and smooth endoplasmic reticulum, with an increase in multivesiculate bodies. Microvilli were significantly shortened, and amorphous electron-dense material was present in the expanded intercellular spaces. The absence of Noroviruses in damaged mucosal cells was noteworthy. The results of light and electron microscopy in volunteers infected with the Hawaii agent were similar, and, again, virus particles were not identified in biopsies (Dolin et al. 1975; Schreiber et al. 1974). In general, *Norovirus* infections seem to cause mild atrophy of the villi of the small intestine, assumed to arise from limited virus replication that damages the mucosal cells. The appearance of mucosal lesions was paralleled by a decrease in brush border enzymes, which returned to normal values during convalescence (Agus et al. 1973).

Epidemiology

Noroviruses are now established as the most important cause of epidemic nonbacterial outbreaks of gastroenteritis worldwide. National surveillance and diagnosis by EM of outbreaks of nonbacterial gastroenteritis in the UK have shown that Noroviruses are a more common cause of infective gastroenteritis than *Salmonella* or *Campylobacter* (Food Standards Agency 2000). The infectious intestinal disease study conducted in England and Wales between August 1993 and January 1996 suggested that at least 600 000 cases of gastroenteritis annually could be attributed to *Norovirus* infections (Food Standards Agency 2000). This figure is likely to be a considerable underestimate, as the relatively insensitive method of EM was chosen for *Norovirus* detection. There has also been an increasing prevalence of Noroviruses in recent years, with a strong suggestion of a winter seasonality culminating with a major epidemic in the UK in January 2002. Similarly, since October 2002 several states in the USA have reported an increase in outbreaks of *Norovirus* infection (www.cdc.gov/mmwr/PDF/wk/mm5203.pdf).

The diversity of settings associated with these economically important viruses is demonstrated by work conducted in the USA soon after the discovery of the Norwalk virus. This virus originally caused a community-wide outbreak in Norwalk, Ohio; Hawaii and Montgomery County agents were responsible for small family outbreaks (Thornhill et al. 1977), whereas the Snow Mountain agent caused an outbreak at a holiday camp in Colorado (Morens et al. 1979). The Taunton agent caused considerable disruption in a hospital in southern England (Caul et al. 1979; Pether and Caul 1983). Subsequent surveillance and investigations of outbreaks in many parts of the world identified the potential of Noroviruses for causing epidemic gastroenteritis in semiclosed or community-wide populations, for example families, healthcare institutions, holiday locations including cruise ships, educational establishments, and the catering industry. Outbreaks occur among children and adults, but rarely among neonates or very young children. Although considerable data are available on the causal role of Noroviruses in outbreaks, less is known about their role in endemic disease, perhaps because of the relative mildness of the illness. Hospitalization of individual cases is thus unusual, and opportunities to investigate sporadic cases are scarce.

Despite the lack of secondary spread by the respiratory route, it is clear that many of the explosive outbreaks described cannot be due solely to fecal–oral transmission. Noroviruses can be detected in vomitus (Greenberg et al. 1979b): the projectile vomiting associated with acute infections and the consequent formation of aerosols offers an alternative mode of spread (Caul 1994a; Chadwick and McCann 1994; Sawyer et al. 1988; Ho et al. 1989). This, in conjunction with the low infectious dose, would explain the rapid, explosive outbreaks commonly observed in semiclosed communities. The epidemiology of *Norovirus* infections should thus include not only person-to-person spread but also mechanical transmission from hand to mouth. The likelihood of spread from inhalation of aerosol by contacts in close proximity to the index case has been suggested but not proven (Caul 1994a).

In addition to these modes of transmission, Noroviruses are often associated with point-source outbreaks (Caul et al. 1993; Kapikian 1994; Okada et al. 1990). In many cases a likely vehicle of transmission has been identified, for example in the USA, contaminated water

supplies – e.g. municipal water, drinking water on cruise ships, recreational swimming water (lake or pool), and commercially produced ice-cubes – have been incriminated (Blacklow and Greenberg 1991; Cukor and Blacklow 1984; Greenberg et al. 1979a). Foodborne outbreaks are well recognized, and food-specific attack rates have incriminated salads, bakery products, fresh fruit, cold foods, sandwiches, and cooked meat The source of the contamination has often been identified as a symptomatic food handler (Pether and Caul 1983; Reid et al. 1988). The secondary attack rate of point-source outbreaks is often high. In the UK, 20–25 percent of *Norovirus* outbreaks were associated with contaminated food (Caul 1994b), and 26 of 38 outbreaks in Japan were considered to be foodborne (Okada et al. 1990). The application of molecular epidemiology (RT-PCR) has increased our knowledge of such outbreaks and the role of the food handler in transmission. The secondary attack rates in outbreaks in the USA reported by the Centers for Disease Control and Prevention (CDC), Atlanta, ranged between 4 and 32 percent, but attack rates of more than 50 percent have often been reported in semiclosed communities. Outbreaks have been prolonged by the introduction of susceptible individuals into an infected environment (e.g. aboard cruise ships and in hospitals).

Contaminated shellfish are a major source of epidemic gastroenteritis (Appleton and Pereira 1977; Christopher et al. 1978; Kaplan et al. 1982; Caul 1994b; Morse et al. 1986). The most commonly reported are the bivalve molluscs (oysters, cockles, and mussels), which are filter-feeders and become infected by Noroviruses from raw sewage. Noroviruses are the major cause of viral gastroenteritis arising from eating shellfish in the UK, and both small and large outbreaks have frequently been reported around the world (Kohn et al. 1995; Le Guyader et al. 2000; Murphy et al. 1979).

Seroepidemiology

The inability to propagate Noroviruses in cell culture and the lack of a suitable animal model severely limited seroprevalence studies in the past. American workers developed a number of crude serological assays, using fecal extracts containing Norwalk virus, to assess the acquisition of Norwalk antibody in different populations (Greenberg et al. 1979a; Kapikian et al. 1978). Antibodies were acquired gradually during childhood, about 20 percent of children under 5 years old being positive. The prevalence of antibody rose rapidly to 45 percent in 18–35-year-olds, and to 55–60 percent in those aged 45–65. These findings are in accordance with the prevalence of *Norovirus* infections in older children and adults, and contrast with those of rotaviruses and *Sapovirus* in developing countries, where antibody is acquired very early in life. In Bangladesh 100 percent of children had acquired antibody by the age of 5, whereas in the former Yugoslavia the seroprevalence rate was intermediate between that of the USA and those of less developed countries (Kapikian 1994); similar results have been reported from Taiwan and the Philippines. The prevalence of Norwalk virus antibody in blood donors in the USA, Belgium, Yugoslavia, and Switzerland ranges from 54 to 77 percent, and emphasizes the ubiquitous nature of this agent. Compelling evidence that Norwalk virus was responsible for many outbreaks throughout the world in the 1970s has been demonstrated by RIA tests (Kapikian 1994). All these studies were performed when Norwalk virus was circulating in the community.

The expression of recombinant Norwalk virus capsid protein (Jiang et al. 1992) in insect cells, and subsequently the expression of the capsid protein from a number of other Noroviruses, has allowed extensive seroepidemiological studies to be performed using defined reagents in an ELISA format. Importantly, it was shown that recombinant Norwalk virus antigen performs identically to natural Norwalk virus antigen purified from feces of infected volunteers (Green et al. 1993). Seroepidemiological studies using recombinant *Norovirus* capsid antigens have yielded generally similar results: newborn to 6-month-old children had higher serum antibody levels than children aged 6–11 months, representing the decay of maternal antibodies in the early months of life (Cubitt et al. 1998; Dimitrov et al. 1997; Gray et al. 1993; Parker et al. 1994; Pelosi et al. 1999). *Norovirus* antibody prevalence increases in the first 2 years of life, reaching 90 percent in individuals over 60 years old. The prevalence of antibodies to genogroup II Noroviruses appears to be greater, and there are some differences in the rate of antibody acquisition between studies. However, it is likely that these assays detect a range of heterologous responses to Noroviruses, rather than antibodies specific for a single virus type.

Some 20 percent of individuals appear to be resistant to *Norovirus* infections (Graham et al. 1994). Norwalk virus VLPs were used in an interesting study to investigate their binding properties to epithelial cells (Marionneau et al. 2002). This study showed that Norwalk virus VLPs attach to the surface of epithelial cells, but only for secretor phenotype individuals, who represent 80 percent of American/European populations. Inactivation of the *FUT2* gene (chromosome 19) is the predominant mutation that defines the nonsecretor phenotype. Competitive binding studies using H1 and/or H3/4 trisaccharides confirmed that Norwalk virus VLPs uses these as ligands for binding to epithelial cells of secretors, and this may in part account for the susceptibilty of the general population. A separate volunteer challenge study (Hutson et al. 2002) showed that patients with the B blood group antigen have a decreased risk of *Norovirus* infection; however, this work did not evaluate the secretor status of the individuals tested. Recently it was shown, using a human challenge model, that 29 percent

of a study population was homozygous recessive for the *FUT2* gene, and that these individuals were resistant to infection following challenge. However, some individuals in the susceptible population were resistant to infection, suggesting an immune component to resistance (Lindesmith et al. 2003).

Laboratory diagnosis

VIRUS ISOLATION

There are no reports of the isolation of Noroviruses in either cell or human intestinal organ cultures. Tests with a wide range of animals have also failed to identify a suitable model (Kapikian 1994), although recently it was reported that macaques could be experimentally infected with human Noroviruses (Subekti et al. 2002). Some success has been achieved with the transmission of Norwalk virus in chimpanzees, in which serological responses and excretion of Norwalk virus antigen in stools were described (Wyatt et al. 1978). It is, however, unlikely that isolation in cell cultures will ever be used for diagnosis, as in vitro methods are too slow and labor-intensive.

ELECTRON MICROSCOPY

EM is the most commonly used laboratory diagnostic method for direct detection of Noroviruses in stools. All Noroviruses are indistinguishable on EM when examined by routine negative staining methods (1.5 percent phosphotungstic acid at pH 6.5). Virions possess an amorphous surface structure, lacking a defined symmetry, with a ragged outline (Figure 7a) that probably explains the wide range of particle diameters (32–38 nm) reported. It is essential that preparations of Noroviruses are examined in the absence of antibody, which can mask the surface structure and lead to incorrect identification (Caul and Appleton 1982).

Noroviruses are commonly excreted in feces as small aggregates and in very low numbers at 10^6 viruses/g of stool (relative to other enteric viral infections, e.g rotaviruses and adenoviruses). These concentrations are close to the limit of sensitivity of the EM, so careful examination of preparations is necessary. Contamination with other proteins in clinical samples often obscures Noroviruses, and can be overcome by applying SPIEM with human convalescent sera. Samples prepared in this way are superior to conventional methods of virus concentration used in EM and significantly increase the detection rate of Noroviruses. SPIEM is as sensitive as molecular methods for detecting Noroviruses (Green et al. 1995) and has the advantage of speed that is so important to the management of outbreaks. EM has the added value of being a 'catch-all' system, whereby all viruses associated with gastroenteritis can be detected. EM will probably retain an important role in the investigation of future *Norovirus* outbreaks, for which rapid diagnosis is a prerequisite.

SEROLOGICAL METHODS

The preparation of hyperimmune antisera to recombinant *Norovirus* capsid antigens has facilitated the development of an EIA for identifying naturally acquired or experimentally induced Norwalk virus antigen and antibody (Jiang et al. 1992; Treanor et al. 1993). Application of these new assays to volunteer studies has provided new insights into Norwalk virus infection (Graham et al. 1994), showing that seroconversions were highest among volunteers who experienced vomiting. The assays for Norwalk virus are highly specific, revealing more subclinical infections, longer periods of virus excretion (up to 7 days), and higher infection rates than were previously recognized (Graham et al. 1994). Subsequent to the development of the Norwalk virus EIA a range of antigen capture EIAs were developed based on polyclonal antisera from different animal species for the capture and detection of *Norovirus* antigens in human fecal specimens (Jiang et al. 1995a, b; Leite et al. 1996; Green et al. 1997; Hale et al. 1999; Vipond et al. 2000).

All these assays show a high degree of type or strain specificity, and as yet it has not been possible to develop a 'catch-all' antigen trap EIA. The EIA format for detection of Noroviruses in clinical specimens offers considerable advantages over RT-PCR. EIA is cheap, rapid, and simple, and thus easy to deploy in the routine diagnostic setting. Recently the first commercially available EIA has been brought to the diagnostic marketplace. This contains a mixture of polyclonal sera for antigen capture and monoclonal antibodies for detection, and is designed to detect a range of both genogroup I and genogroup II human Noroviruses.

RT-PCR

The characterization of the *Norovirus* genome has allowed the application of molecular techniques to the diagnosis of *Norovirus* infection. The scientific literature now abounds with RT-PCR-based studies. Most diagnostic RT-PCR approaches are based on the RNA polymerase and capsid regions of Noroviruses. Both these regions show considerable heterogeneity, allowing the division of human strains into a minimum of two genetic groups (Green et al. 1994) and many different clusters or clades. Molecular epidemiology is a powerful tool for the investigation of point-source outbreaks, particularly for examining shellfish (Atmar et al. 1993) and in monitoring the spread of Noroviruses (Green et al. 1995). These techniques are not used for routine diagnosis because of cost considerations and the need for specialized laboratory equipment (e.g. thermal cyclers), and are thus restricted to the research or reference laboratory.

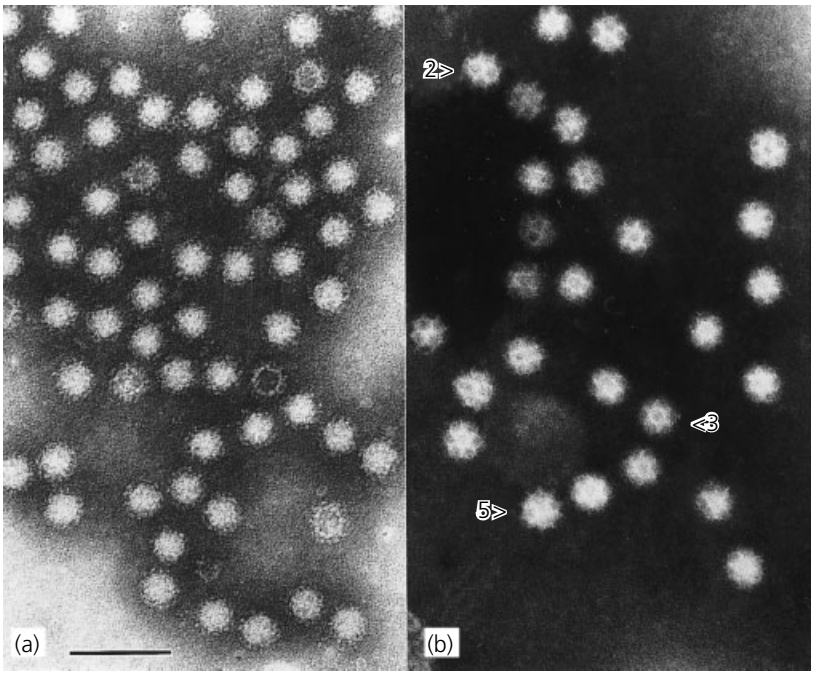

Figure 7 *Electron microscopic appearance of human enteric caliciviruses.* **(a)** *Noroviruses lack the distinctive surface morphology characteristic of Sapoviruses, although a ragged edge is clearly visible surrounding some of the particles.* **(b)** *The distinctive surface structures on a* Sapovirus *viewed along the two-, three- and fivefold (indicated) axes of symmetry. Bar, 100 nm for each panel.*

An electronic system (CaliciNet) has been developed at CDC Atlanta to fingerprint strains of Noroviruses that are associated with foodborne outbreaks (www.cdc.gov/foodsafety/fsactivities.htm).

Prevention and control

In volunteers, Noroviruses induce both short- and long-term immunity but, until the mechanisms are fully understood, it is unlikely that a vaccine can be developed (Green et al. 1995).

The high infectivity of Noroviruses and the explosive outbreaks of gastroenteritis that often occur in semi-closed communities present a major challenge to control of infection and require aggressive intervention (Caul 1994a; Chadwick and McCann 1994). Measures for interrupting the various modes of transmission (see Epidemiology) must include 'enteric' precautions, but these alone are ineffective and should be supplemented by measures to deal with patients who vomit (Chadwick et al. 2000). Symptomatic healthcare workers should be excluded from contact with patients for at least 2 days after resolution of symptoms. Effective handwashing should be routine. People caring for patients should wear disposable gloves, gowns, and masks when cleaning vomit, fecal material, or contaminated clothing. Soiled linen and clothes should be handled carefully, to minimize the generation of aerosols, and transported in plastic bags to the laundry. All potentially contaminated surfaces in toilets, bathrooms, and rooms occupied by patients should be disinfected with a chlorine-based product and cleaned with a hot detergent solution. Contact with other patients should be avoided.

Common-source outbreaks are well documented. Symptomatic food handlers have often been incriminated and must be excluded from the workplace for at least 2 days after resolution of symptoms. Decontamination of all potentially infected surfaces in the kitchens and associated rest and toilet facilities is essential (Caul et al. 1993). Suspect water supplies may require shock chlorine treatments. Shellfish are a particular problem in the transmission of Noroviruses, and the most effective preventive measure is to cultivate them in clean water, as depuration processes are not effective in eliminating Noroviruses from shellfish.

SAPOVIRUSES

Distinctive virus particles 30-40 nm in diameter and differing from both astroviruses and the Noroviruses were first recognized in fecal samples by negative staining techniques in 1976 (Madeley and Cosgrove 1976). These viruses, displaying a distinctive typical calicivirus morphology, have since been assigned to a separate genus (*Sapovirus*). Viral particles viewed along their threefold axes of symmetry possess a central stain-filled cup (calyx) surrounded by six peripheral cups, giving rise to the 'star of David' appearance. Viewed along their two-fold axes of symmetry they have four cups (Figure 7b). Particles viewed along their fivefold axes present as 10-pointed spheres and may not be identified

so readily as the classic particles described above. Unlike astroviruses, which possess a smooth, entire edge, caliciviruses have a ragged outline which makes accurate measurement difficult, and explains the particle diameters of 31–38 nm quoted by most workers. Sapoviruses have a buoyant density of 1.37–1.38 g/cm^3 (Terashima et al. 1983). The history of these viruses has been reviewed (Chiba et al. 2000). The significance of molecular data to differentiate between classic caliciviruses and Noroviruses was first recognized in our laboratory (Lambden et al. 1994). Further extensive sequencing studies have shown that the classic caliciviruses have a different genome structure from the Noroviruses, and phylogenetic analysis clearly places them in a different genus. The prototype strain *Sapporo virus* was isolated from an orphanage in Sapporo, Japan (Chiba et al. 1979).

Detailed ultrastructural studies on caliciviruses showing the typical morphology have been performed only on animal caliciviruses (Prasad et al. 1994; Zheng et al. 2001). The three-dimensional structure of the viruses was determined by cryo-electron microscopy and computer image-processing techniques. The primate calicivirus virions are 40 nm in diameter and have a T = 3 icosahedral symmetry, with 32 surface depressions at the five- and three-fold axes of symmetry (Figure 2). The surface depressions are surrounded by 90 archlike capsomers, each of which is a capsid protein, in an arrangement similar to that seen in the Noroviruses.

Genome organization

Sequence analyses of isolates of Sapoviruses from the UK, USA, and Japan have been used to assign this group of viruses to a separate genus (Berke et al. 1997; Jiang et al. 1997; Lambden et al. 1994; Liu et al. 1995; Matson et al. 1995; Noel et al. 1997; Vinjé et al. 2000).

Only two complete genome sequences of human *Sapovirus* (UK/Manchester/93; UK/Bristol/98) have so far been described (Liu et al. 1995, 1997; Robinson et al. 2002), and the sequence and genome organization of these viruses support their allocation to a genus separate from the Noroviruses. The complete sequence of the Manchester isolate consists of 7 431 nt, with the first predicted in-frame AUG codon at position 13. The 3′ end of the genome contains 84 untranslated nucleotides, followed by a polyadenylate tail. The genetically distinct Bristol isolate has a genome of 7 490 nt, with the predicted translation initiator codon at position 14. The 3′ untranslated region of Bristol virus consists of 140 nt preceding the poly (A) tail. The small ORF overlapping the start of the capsid encoding region of the genome of Manchester virus was not present in the Bristol isolate, suggesting that this region of the genome may not encode a biologically active product. This overlapping sequence was also missing from the closely related London/92 isolate (Jiang et al. 1997). In common with all caliciviruses examined to date, Sapoviruses also possess the small 3′ terminal ORF. Sequence comparisons and phylogenetic analyses suggest that the Sapoviruses form distinct genetic clusters in a manner analogous to the Noroviruses (Berke et al. 1997; Vinjé et al. 2000). A recent analysis has suggested that there may be two discrete genetic clades of human Sapoviruses, together with genetically distinct animal counterparts (Robinson et al. 2002), mirroring the situation in the *Norovirus* genus (Figure 5).

A fundamental difference between Noroviruses and Sapoviruses is that the region of the genome predicted to encode the structural capsid protein of Sapoviruses is in the same frame as ORF1 and contiguous with the RNA polymerase coding region, resulting in one large fused polyprotein (Figure 8). This genome organization is also found in the rabbit hepatotropic calicivirus, RHDV, and contrasts with those of all Noroviruses sequenced to date. The consequence of such a genome organization is that an additional proteolytic cleavage is required to release the RNA polymerase from the capsid protein.

A major feature that distinguishes the caliciviruses from the picornaviruses is the production of one or more species of subgenomic RNAs during replication. In the case of RHDV, a subgenomic RNA is also encapsidated into mature virus particles (Meyers et al. 1991; Zheng et al. 2001). The existence of a subgenomic RNA has not been established for Sapoviruses, and only indirect evidence exists for Norwalk virus. The 5′ terminal sequences of the putative subgenomic RNAs share sequence homology with the 5′ genomic RNA termini, although the level of sequence identity was less than the analogous conserved motifs observed both for Noroviruses and animal caliciviruses. The conservation of sequence motifs suggests an important regulatory role for these regions of the genome, perhaps serving as promoters for the synthesis of genomic and subgenomic RNAs from negative-strand intermediates.

Viral proteins

The lack of a productive cell culture system for Sapoviruses and the resistance of adults to experimental infection (Cubitt 1994) has greatly impeded analysis of the viral polypeptides. During acute infection the viruses are, however, shed in relatively high concentrations. A single fecal specimen obtained during an outbreak of acute gastroenteritis in an orphanage in Sapporo, Japan, was used for the purification of virions (Terashima et al. 1983). This study showed that classic *Sapovirus* particles contain a single polypeptide of 62 kDa that could be precipitated with convalescent (4 weeks) but not acute-phase (2 days) serum from the same patient.

The large ORF1 has a coding potential of 2 280 amino acids and includes conserved motifs typical of the 2C NTPase, 3C protease, and 3D RNA polymerase in

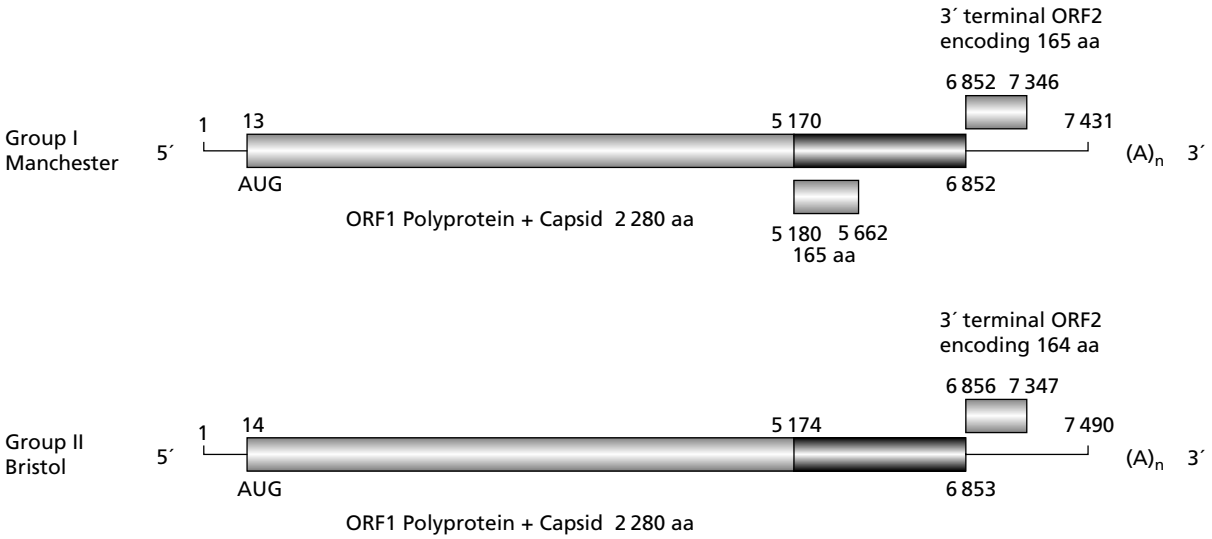

Figure 8 *Comparison of the genome structures of groups I and II Sapoviruses (Manchester, EMBL/GenBank Accession No. X86560; Bristol, EMBL/GenBank Accession No. AJ249939). Shaded boxes represent computer-predicted open reading frames. Translation products and their sizes are indicated on the open reading frames. The darker shaded area at the 3′ terminus of ORF1 represents the capsid coding region which is fused to the ORF1 nonstructural polyprotein. In group I Sapoviruses an additional small protein (161 aa) encoded in an alternative reading frame is predicted within the capsid coding region.*

relative genomic positions similar to those of other caliciviruses. Sequence comparisons of Sapoviruses with other caliciviruses, including the Noroviruses, show only 20–40 percent amino acid identity in the functional domains of the nonstructural polyprotein. Relatively little is known about polyprotein processing in Sapoviruses, except that in vitro protein synthesis in a coupled transcription translation reaction yields a very different cleavage pattern from the Noroviruses (Clarke and Lambden 2000). The exact cleavage dipeptide has not been experimentally determined for Sapoviruses, but it is likely that these viruses will show a similar site preference for EG residues.

Clinical manifestations

Symptomatic *Sapovirus* infection occurs most often in infants and young children, and appears indistinguishable from the milder forms of rotavirus infection (Cubitt 1987; Cubitt and McSwiggan 1981; Sakai et al. 2001; Suzuki et al. 1979). Transmission is by person-to-person spread through the fecal–oral route, and this is probably important in maintaining an endemic state in some semi-closed communities. Contaminated shellfish, cold foods, and drinking water have also been implicated as vehicles of infection (Cubitt 1988).

The incubation period is 1–3 days and symptoms persist for an average of 4 days. Diarrhea and vomiting are common, whereas fever with upper respiratory symptoms is less so. There is no evidence that Sapoviruses replicate in respiratory mucosal cells or that respiratory spread occurs. As respiratory symptoms have been described mainly in young children, they may arise from one of the concomitant respiratory viral infections common in this age group.

Pathogenesis

In contrast to Noroviruses there have been no reports of ultrastructural studies of human *Sapovirus* infections in the gut. Analogy with all the other 'diarrhea viruses' would suggest that human Sapoviruses replicate in mucosal cells lining the villi of the small intestine. In limited adult volunteer studies the virus was administered by the nasal/oral route (Cubitt 1994). Symptoms were inapparent, or ranged from mild to moderately severe, where the latter included nausea, vomiting, diarrhea, pyrexia, and abdominal pains. These clinical features resemble those in naturally acquired infections.

Epidemiology

Most of our data on the epidemiology of Sapoviruses derives from EM observations and seroprevalence studies using purified viruses or hyperimmune sera in blocking ELISAs, although latterly some RT-PCR surveys have been conducted. When the Sapoviruses were first discovered it was not possible to assign a causal role because 20 percent of children excreting them were asymptomatic. Subsequently, an outbreak of gastroenteritis in an infant and junior school in north London was investigated and a *Sapovirus* was shown to be the causal agent (Cubitt et al. 1979) This outbreak was mistakenly described as 'winter vomiting disease,'

although spread to others in the school and to home contacts was negligible, being perhaps limited by their immunity. These epidemiological and immunological features are not consistent with 'winter vomiting disease' caused by Noroviruses. Sapoviruses have since been established as enteric pathogens (Christensen 1989; Cubitt 1994). In children hospitalized with sporadic diarrhea, excretion rates of 0.9–6.6 percent have been reported (Cubitt and McSwiggan 1981; Suzuki et al. 1979). A similar excretion rate (2.9 percent) was reported in a daycare center in the USA (Matson et al. 1989). All these studies suggest that Sapoviruses are a minor cause of clinically significant disease. In contrast with infection in older children, neonatal infection is often subclinical (Matson et al. 1990). These observations are supported by data from the IID study in England and Wales which showed that Sapoviruses were found most frequently in children between the ages of 1 and 4 years, and constituted 7 percent of the viruses identified in the general practice component of this study (Food Standards Agency 2000). This is in agreement with an RT-PCR survey conducted in Japan, where 6.6 percent of patients with gastroenteritis were positive for Sapoviruses (Okada et al. 2002), and a survey of children aged 2–24 months in Finland, where 9.2 percent of stool specimens were positive (Pang et al. 2001).

Sapovirus infections are endemic in the UK, usually appearing sporadically in young children, although community and nosocomial outbreaks have also been recognized. Outbreaks have been reported in Japan (Chiba et al. 1979; Oishi et al. 1980), Australia (Grohmann et al. 1991), England (Cubitt et al. 1979, 1980; Cubitt and McSwiggan 1981; Gray et al. 1987; Humphrey et al. 1984), Canada (Spratt et al. 1978), and Scandinavia (Kjeldsberg 1977), not only among children but also among elderly patients in nursing homes, where the attack rates ranged from 50 to 70 percent. Outbreaks among adults and elderly patients are unusual and may represent infections that have arisen because of waning immunity. A distinct seasonality has not been described for *Sapovirus* infections, primarily because too few cases were reported from which to analyze seasonality.

Seroepidemiology

Progress in understanding the seroepidemiology of Sapoviruses has been dependent on using viruses from fecal specimens. Attempts at expression of the human *Sapovirus* major capsid protein in insect cells using recombinant baculoviruses have met with mixed fortunes. Whereas some laboratories have reported success in obtaining recombinant VLPs with a structure and morphology similar to those of the native virions, in most cases these VLPs are unstable. Fortunately, it has been possible to purify sufficient *Sapovirus* particles from stool samples to produce diagnostic antigen trap ELISAs. Such an ELISA was also used in a blocking assay presenting captured antigen from stool specimens to measure antibodies to Sapoviruses in 128 serum samples from an age-stratified population from the USA. This important study showed a high incidence of antibody in young children, reaching 100 percent in the 4–6-year age group (Nakata et al. 1988). Thus immunity to Sapoviruses appears to be long-lived, in sharp contrast to *Norovirus* infections, where the short-term immunity allows symptomatic reinfections (Greenberg and Matsui 1992).

In Japan, antibody to *Sapovirus* is rapidly acquired between 6 months and 2 years of age, with a prevalence of 30 percent, rising to 65 percent in 2–5-year-olds and approximately 90 percent in older children and adults (Nakata et al. 1985; Sakuma 1981). Tests on pooled γ-globulin and serum samples in all continents confirm these findings (Christensen 1989). The high seroprevalence in early childhood agrees with the reported excretion rates of Sapoviruses in young children. The paucity of reports of *Sapovirus* infection in hospitalized children with diarrhea suggests that asymptomatic – or at least clinically insignificant – disease in childhood is common.

Laboratory diagnosis

VIRUS ISOLATION

Human Sapoviruses cannot be grown in cell culture, although there is a single report of serial propagation of human *Sapovirus* in dolphin kidney and HEK cells in the presence of trypsin (Cubitt and Barrett 1984). In this work, cytoplasmic replication was demonstrated by immunofluorescence and by radiolabeling of polypeptides. This report has not been confirmed, and many other workers have failed to propagate human Sapoviruses in vitro.

ELECTRON MICROSCOPY

The unique morphology of Sapoviruses allows definitive identification by EM (Madeley 1979), and micrographs should always be checked to confirm direct observations with the EM. The characteristic morphology has been the main criterion for identifying Sapoviruses. If the morphology suggests a *Sapovirus* but is not convincing, RT-PCR analysis may confirm the diagnosis (Honma et al. 2000; Robinson et al. 2002). EM is currently the only routine method available for laboratory diagnosis, and requires skilled operators to achieve consistent results.

IMMUNOASSAYS

The need for alternative methods of identifying caliciviruses in stool samples has been generally recognized.

Nakata and co-workers (Nakata et al. 1983) found that a solid-phase RIA using a hyperimmune guinea-pig serum was more sensitive than EM. This assay was later modified to an EIA of similar sensitivity (Nakata et al. 1988). No commercially produced ELISA tests are available to the routine laboratory.

SEROLOGY

Specific IgM, seroconversions or rising titers of specific IgG have been observed following infection (Chiba et al. 1979; Cubitt et al. 1979; Cubitt et al. 1980; Cubitt et al. 1981; Nakata et al. 1985; Sakuma 1981). These techniques, although useful in epidemiological studies, are not ethically justified for diagnosing enteric 'diarrhoea virus' infections in young children because they involve taking blood samples.

PREVENTION AND CONTROL

The measures needed to prevent the spread of calicivirus infections are the same as those recommended in the previous section on Prevention and control.

ANIMAL ENTERIC CALICIVIRUSES

Following the discovery of human enteric caliciviruses similar viruses were found in cattle and swine. These viruses were either observed directly by EM or, in some cases, their presence was inferred by a positive polymerase chain reaction (PCR). With improved detection technology it is likely that other mammalian enteric caliciviruses are yet to be discovered, and although there is no evidence for cross-species infection, an animal reservoir for human infection remains a possibility.

Noroviruses

Early studies revealed the presence of viruses resembling Noroviruses in fecal specimens from cattle (Almeida et al. 1978; Granzow and Schirrmeier 1985; Günther et al. 1984; Woode and Bridger 1978). The first bovine Noroviruses were described in England and, following the tradition established for the human Noroviruses, are called Newbury agents 1 and 2 after the geographical location where they were discovered (Woode and Bridger 1978). The Newbury agent 1 (NA1), like the human Noroviruses, has a single major capsid protein (Dastjerdi et al. 2000). Following the discovery of the Newbury agents similar viruses were also found by two independent groups in the former East Germany (Granzow and Schirrmeier 1985; Günther et al. 1984). Since these early studies the application of RT-PCR to fecal specimens from farm animals has revealed the presence of *Norovirus*-like sequences in both swine (Sugieda and Nakajima 2002; Sugieda et al. 1998) and cattle (van der Poel et al. 2000).

The complete genome sequence of a bovine virus (Jena virus (JV)) has been determined (Liu et al. 1999a) and shows that the JV genome organization is very similar to that of the human Noroviruses. Sequence analysis of the capsid region of Newbury agent 2 (NA2) has confirmed the relationship of the bovine Noroviruses to the human Noroviruses, and phylogenetic analysis suggests that the bovine Noroviruses belong to a distinct genetic group (Belliot et al. 2001). Bovine Noroviruses do not grow in cell culture; however, calves have been used in an experimental setting to study infection. Newborn calves and calves up to 60 days of age are susceptible to infection with bovine Noroviruses (Bridger 1990). Virus replication occurs in the enterocytes of the small intestine, showing a similar tissue and cell tropism to that observed for human Noroviruses (Hall et al. 1984).

EM studies from the 1980s suggested that bovine Noroviruses are 'commonly found in the British calf population' (Bridger et al. 1984). Recently the capsid protein of JV has been expressed in insect cells using a recombinant baculovirus vector. The protein assembled to form VLPs, and this allowed the development of a diagnostic ELISA and an ELISA to study the seroprevalence of JV. The antigen capture ELISA was used to survey fecal specimens collected from calves in dairy herds in Germany, and showed that 8.9 percent of the samples were positive for JV infection. Seroepidemiological data from the same study indicated that 99.1 percent of cattle have antibodies to JV. The very high seroprevalence for JV suggests that bovine *Norovirus* infections are endemic, and the high antibody levels in older cattle suggests that they are constantly re-exposed to infection. These observations, coupled to the findings of RT-PCR surveillance in other countries which has identified *Norovirus* sequences in bovine and swine, confirms the widespread nature of *Norovirus* infections, and it would seem likely that Noroviruses remain to be found infecting other mammalian species. It has been suggested that animal Noroviruses could be a source of infection for humans. Although there are no data on the susceptibility of humans to animal *Norovirus* infections (with the exception of a single report), no human Noroviruses have been shown to infect and cause disease in other mammalian species. Thus the bovine system may provide an important animal model for studying the human viruses.

A bovine calicivirus morphologically indistinguishable from the Noroviruses was recently sequenced in the USA (Smiley et al. 2002). This virus (BEC NB) was originally observed in 1980, along with a coronavirus, in a fecal specimen from a calf in Nebraska, Ohio. However, the genome organization of BEC NB resembled that of the Sapoviruses, with the ORF1 polyprotein fused to and contiguous with the capsid encoding region of the genome. In experimental infections of calves, BEC NB showed similar intestinal lesions and tropism to the bovine Noroviruses. Phylogenetic analysis

suggests that BEC NB may be a representative of new genus of enteric caliciviruses.

Sapoviruses

Membership of the *Sapovirus* genus is defined on the basis of phylogeny and the organization of the viral genome. An enteric calicivirus infecting swine was first described in the USA in 1980 (Saif et al. 1980). Experimental infections with this virus (Cowden PECV) using gnotobiotic piglets established a causal role in enteric disease. Infection results in villous atrophy and profuse diarrhea. The adaptation of Cowden PECV to growth in cell culture marked an important and significant breakthrough in calicivirus research, as this is the only enteric calicivirus that can be cultured. Following serial passage through gnotobiotic piglets the virus was adapted to grow in primary porcine embryonic kidney cells (Flynn and Saif 1988), and then in a continuous pig kidney cell line (Parwani et al. 1991). The key factor in this success was the incorporation of the intestinal contents of uninfected gnotobiotic piglets into the cell culture medium. The growth-promoting factors of the intestinal contents of piglets have been investigated in depth (Chang et al. 2002). Pretreatment of cells or PECV prior to infection (30 min) with intestinal contents, followed by removal, failed to support viral growth, suggesting that cells needed constant signaling/stimulation from intestinal contents to allow viral growth. Transfection with synthetic genomes of PECV (bypassing receptor binding by the virus) only produced infectious progeny when intestinal contents were continually present. However, the addition of suramin, together with other adenylate cyclase inhibitors, restricted the growth-promoting effect of intestinal contents, suggesting that replication of PECV is dependent on a cAMP signaling pathway that is induced by intestinal contents. Interestingly, the cell culture-adapted virus did not produce clinical disease in experimentally infected piglets (Guo et al. 2001b), suggesting that the cell culture adaptation process had attenuated the virus. The complete genome sequences were determined for wildtype (wt) and cell culture-adapted strains (tc) of Cowden PECV. The genome organization of Cowden PECV conforms closely with that of human Sapoviruses (see Genome organization). PECV tc showed two silent mutations and two amino acid changes in ORF1, and five nucleotide changes in the capsid that result in four amino acid changes compared to PECV wt. It was speculated that the changes in the capsid sequence are responsible for the attenuation of the cell culture-adapted virus (Guo et al. 1999) The capsid protein of Cowden PECV has been expressed in insect cells using a recombinant baculovirus, and undergoes spontaneous assembly to form virus-like particles that are morphologically and antigenically similar to the native virus (Guo et al. 2001c). Insect cells infected by the recombinant baculovirus were used to investigate seroresponses of experimentally infected piglets, and an antigen trap ELISA was developed using hyperimmune sera raised to the VLPs. A preliminary survey using this ELISA showed that variants of PECV were circulating in local swine herds.

It seems likely that there are as yet undiscovered Sapoviruses infecting other animal species. Confirmation that a candidate calicivirus belongs to the *Sapovirus* genus requires phylogenetic and genome organization analyses. An enteric calicivirus was described in mink, but this virus could not be grown in cell culture. RT-PCR of a fragment of the *RNA polymerase* gene showed that the mink virus was closely related to PECV (Guo et al. 2001a). However, the mink from the farm where the virus was discovered had been fed raw offal from pigs, casting doubt on the precise origin of the virus.

Reoviruses, orbiviruses, and coltiviruses

TERENCE S. DERMODY AND ULRICH DESSELBERGER

Introduction and general classification	1	Coltiviruses	11
Reoviruses	2	References	12
Orbiviruses	8		

INTRODUCTION AND GENERAL CLASSIFICATION

The *Reoviridae* family contains ten genera:

- *Orthoreovirus*, *Rotavirus*, *Orbivirus*, all infecting animals and humans
- *Coltivirus* infecting insects, rodents, and humans
- *Aquareovirus* infecting fish and molluscs
- *Cypovirus* infecting insects
- *Fijivirus*, *Phytoreovirus*, and *Oryzavirus* infecting plants and insects (Mertens et al. 2000; Nibert and Schiff 2001).
- *Seadornavirus* infecting insects and humans (Attoui et al. 2000)

In this chapter *Orthoreovirus* is called **reovirus**, the term being an acronym derived from **r**espiratory, **e**nteric, **o**rphan viruses. Only the mammalian genera are discussed; the rotaviruses are reviewed in Rotaviruses.

Members of the *Reoviridae* have the following features in common:

- They contain a genome of 10–12 segments of double-stranded RNA (dsRNA).
- They form icosahedral, nonenveloped particles of approximately 70–80 nm in diameter with a double- or triple-shelled capsid.
- They replicate in the cytoplasm of cells without complete uncoating, produce 5′ end-capped, non-polyadenylated mRNAs, and form intracytoplasmic inclusion bodies.

In comparison to many other viruses, the *Reoviridae* are relatively resistant to inactivation by heat, lipid solvents, and a wide range of pH (with the exception of the orbiviruses, which lose infectivity at low pH).

Full-length sequences of the genomes of several strains of reo-, rota-, and orbiviruses are known, and the protein-coding assignments have been established. The overall genome size in bp (genomic molecular mass in kDa) is 23 540 bp (7 770 kDa) for reoviruses (type 3 reovirus), 18 555 bp (6 120 kDa) for rotaviruses (SA 11 rotavirus), and 19 218 bp (6 340 kDa) for orbiviruses [bluetongue virus type 10 (BTV 10)] (Mertens et al. 2000). The 5′ and 3′ untranslated regions (UTR) of all reovirus RNAs are short (reovirus: 5′-UTR 13–32 nt, 3′-UTR 35–83 nt; rotavirus: 5′-UTR 9–49 nt, 3′-UTR 17–182 nt; orbivirus: 5′-UTR 11–34 nt, 3′-UTR 31–116 nt).

Reoviruses have been isolated from humans but are rarely associated with disease. They cause systemic disease in rodents (mice), and the mouse model of reovirus infection has been used extensively to study mechanisms of viral pathogenesis (Virgin et al. 1997). Rotaviruses are the major cause of infantile gastroenteritis worldwide and the causative agent of acute diarrhea in the young of many mammalian species (e.g. calves, piglets, and lambs). Orbiviruses mainly infect animals, producing severe disease (e.g. African horse sickness, epizootic hemorrhagic disease in cattle and deer, and bluetongue disease in sheep). *Coltivirus* causes Colorado tick fever in humans. Mammalian reoviruses have a broad host range and frequently contaminate water supplies. Rotaviruses are most commonly spread by the fecal–oral route, and orbiviruses are transmitted by a variety of ticks and mosquitoes.

REOVIRUSES

Genome, gene protein assignment, and structure

Orthoreoviruses (reoviruses) are found worldwide in a wide range of vertebrates. They cause hepatic and neurological disease in mice, diarrhea in cattle and sheep, and respiratory tract infections in dogs. In birds, reovirus infections are associated with hepatitis, arthritis, and diarrhea. There are three serotypes of mammalian reovirus, each represented by a prototype strain isolated from a human host: type 1 Lang (T1L), type 2 Jones (T2J), and type 3 Dearing (T3D).

The reovirus genome consists of ten segments of dsRNA that fall into three size classes, which for strain T3D are: large (L), 3 854–3 916 bp; medium (M), 2 203–2 304 bp, and small (S) 1 189–1 416 bp (Nibert and Schiff 2001). The viral proteins are designated according to size: **λ** for proteins encoded by large gene segments, **μ** by medium segments, and **σ** by small segments. Each gene segment is monocistronic with the exception of the *S1* gene, which encodes the viral attachment protein, σ1, and a small nonstructural protein, σ1s. Several protein products are modified post-translationally. The genome segments, their size in bp, and the size, number of molecules, and location in the virion, post-translational modifications, and some of the recognized functions of the protein products are shown in Table 1.

Reovirus virions consist of two concentric protein shells, called outer capsid and core. Three different types of reovirus particles are formed during the process of viral disassembly (Figure 1, p. 4):

1. Virions contain the full complement of eight structural proteins. These represent the infectious form of the virus and are capable of spread from host to host.
2. Infectious subvirion particles (ISVP) lack **σ**3, contain particle-associated cleavage fragments of **μ**1 called **δ** and **ϕ**, and have an extended form of **σ**1. ISVPs are formed in the intestinal lumen or in the endocytic pathway.
3. Cores are devoid of outer-capsid proteins. These particles are enzymatically active and catalyze synthesis of viral RNA.

There are 11 reovirus proteins, eight structural proteins (λ1, λ2, λ3, μ1, μ2, σ1, σ2, and σ3) and three nonstructural proteins (μNS, σNS, and σ1s). Image reconstructions of cryo-electron micrographs of reovirus particles (Metcalf et al. 1991; Dryden et al. 1993, 1998) (Figure 1) combined with X-ray crystallographic analysis of cores (Reinisch et al. 2000) and outer-capsid proteins (Olland et al. 2001; Chappell et al. 2002; Liemann et al. 2002) have revealed the particle structure in great detail. The core lattice is formed by 120 copies of λ1. Channels of λ1 are found at the fivefold symmetry axes of the icosahedral core particle. The λ3 (12 copies) and μ2 (20 copies) proteins are located at the internal aspect of these channels. The λ3 protein is the viral RNA-dependent RNA polymerase (RdRp) and is closely associated with the ten segments of genomic dsRNA. The crystal structure of λ3 reveals a cage-like molecule, with independent channels for template and product (Tao et al. 2002). On top of the λ1 shell are 150 copies of σ2 that act as a clamp to stabilize the λ1 lattice. The λ2 protein (60 copies) forms pentamers at the fivefold symmetry axes. 'Turrets' of λ2 reach to the outer capsid. The λ2 protein plays an important role in viral RNA synthesis by serving as the capping enzyme complex. The outer shell is formed by 600 copies of μ1 and 600 copies of σ3 that interact extensively to form heterohexamers (Liemann et al. 2002). The μ1 protein is myristoylated at its N terminus and is involved in viral penetration of host-cell membranes. The σ3 protein serves as a protective cap for μ1 and renders the virus stable in the environment. The σ1 protein (36 copies) is the viral attachment protein and forms trimers at the icosahedral vertices. The N terminus of σ1 is embedded in the turrets of λ2.

Replication

The reovirus replication cycle is entirely cytoplasmic (Figure 2, p. 4). Many of the features of reovirus replication are similar, though not identical, to those of rotaviruses (for further details, see Nibert and Schiff 2001 and Rotaviruses).

Reovirus infection is initiated by the binding of the σ1 protein to cell-surface receptors. The σ1 protein is a trimer consisting of an elongated fibrous domain – the tail – that inserts into the virion and a virion-distal globular domain – the head (Fraser et al. 1990). Type 3 σ1 contains two receptor-binding domains, one in the head that binds to junctional adhesion molecule 1 (JAM1) (Barton et al. 2001b) and another in the tail that binds α-linked sialic acid (Chappell et al. 2000). In T3D σ1, these domains are dissociable by treatment of σ1 with intestinal proteases, such as trypsin or chymotrypsin (Nibert et al. 1995). Type 1 σ1 binds cell-surface carbohydrate as well, but this molecule has not been identified. For sialic-acid-binding reovirus strains, the initial interaction between the viral particle and the host cell is likely mediated by sialic acid due to the high surface concentration of this carbohydrate (Barton et al. 2001a). By virtue of its rapid association rate, virus binding to sialic acid likely adheres the virion to the cell surface, thereby enabling it to diffuse laterally until it encounters JAM1. Such an adhesion-strengthening mechanism of viral attachment has been shown for several other viruses including herpesviruses and lentiviruses.

Table 1 *Gene protein assignments and functions of mammalian reovirus proteins (T3D)*

RNA		Proteins					
Segment	Size (bp)	Designation	Size (kDa)	Number of molecules/virion	Location	Modification	Functions
L1	3 854	λ3	142	ca. 12	Core	. . .	RdRp
L2	3 916	λ2	145	60	Core spike (outer capsid)	. . .	Guanylyltransferase; methyltransferases
L3	3 901	λ1	143	120	Core	Zn metalloprotein	Binds RNA; NTPase? RNA helicase? RNA triphosphatase?[a]
M1	2 304	μ2	83	ca. 20	Inner capsid	. . .	Binds RNA; NTPase?
M2	2 203	μ1	76	600	Outer capsid	N-myristoylated	Role in penetration and transcriptase activation
		μ1C	72	. . .	. . .	Cleavage product of μ1	. . .
M3	2 241	μNS	80	. . .	Nonstructural	Phosphoprotein	ssRNA-binding; core binding; role in RNA assortment or replication?
		μNSC	75	. . .	Nonstructural	. . .	Unknown
S1	1 416	σ1	49	36	Outer capsid	. . .	Viral attachment protein; hemagglutinin; type-specifying antigen
		σ1s	14	. . .	Nonstructural	. . .	Unknown (dispensable in cell culture)
S2	1 331	σ2	47	150	Inner capsid	. . .	Binds ds RNA
S3	1 198	σNS	41	. . .	Nonstructural	. . .	ssRNA-binding; role in assortment or replication?
S4	1 196	σ3	41	600	Outer capsid	Zn metalloprotein, sensitive to protease degradation	dsRNA-binding; effects on translation

Modified from Nibert and Schiff 2001.

a) Possibly encoded by the M1 gene segment μ2 protein (Tao et al. 2002).

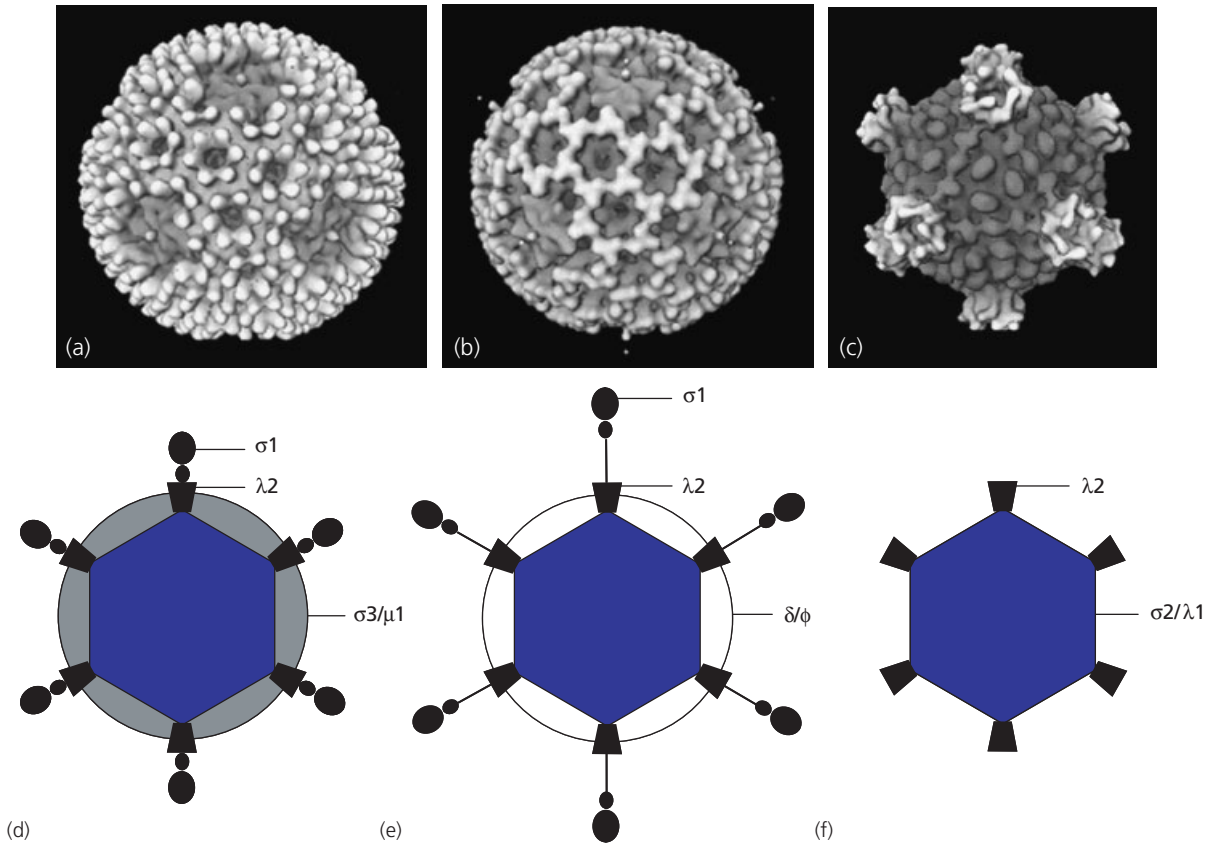

Figure 1 *Reovirus virions, ISVPs, and cores.* **(a–c)** *Surface-shaded views of the reovirus strain T1L* **(a)** *virion,* **(b)** *ISVP, and* **(c)** *core. The images were obtained using cryo-electron microscopy and three-dimensional image reconstruction. Each particle is viewed along a threefold axis. Figure modified from Centonze et al. 1995 with permission.* **(d–f)** *Schematic representations of reovirus* **(d)** *virion,* **(e)** *ISVP, and* **(f)** *core. Major viral structural proteins are indicated.*

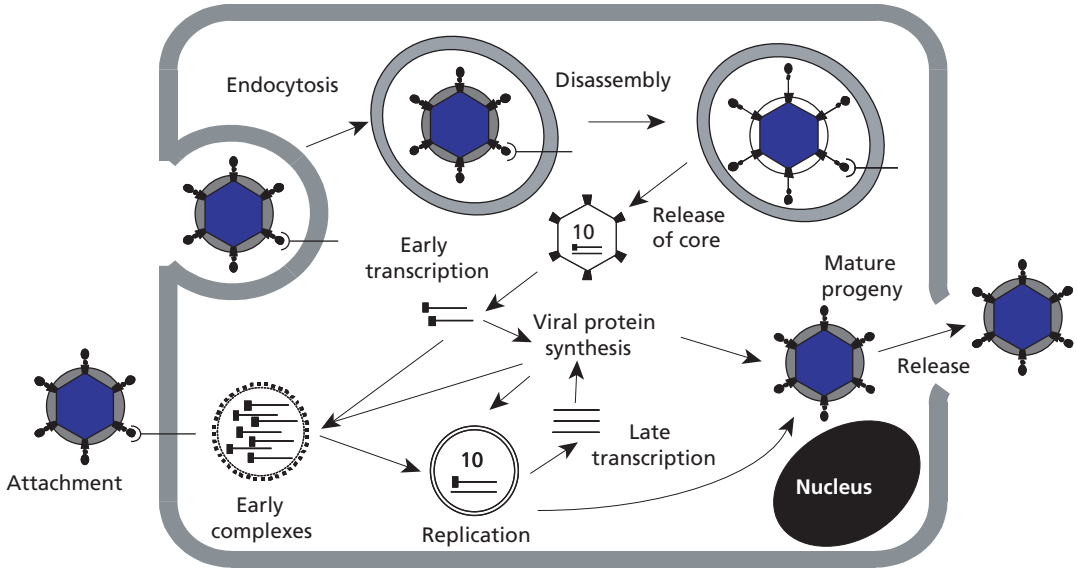

Figure 2 *The reovirus replication cycle. Reovirus virions attach to cellular receptors and enter cells by receptor-mediated endocytosis. Within an endocytic compartment, the viral outer capsid is removed to generate ISVPs. ISVPs penetrate membranes of endocytic vesicles and release the viral core into the cytoplasm. Transcription of the viral genome occurs within the core, and nascent mRNAs are released through turret-like openings at the viral vertices. Viral mRNAs are used as template for viral protein synthesis and replication of viral genomic dsRNA. Particles containing dsRNA segments are termed replication particles. These particles are transcriptionally active and yield additional viral mRNAs, resulting in an amplification of viral protein synthesis. Following addition of viral outer-capsid proteins to the replication particles, progeny virions are assembled and exit the cell.*

Following attachment to cell-surface receptors, reovirus enters cells by receptor-mediated endocytosis. In the endocytic compartment, virions undergo proteolysis by endocytic proteases, resulting in generation of ISVPs. The endocytic cysteine-containing proteases cathepsin B and cathepsin L convert virions to ISVPs in mouse fibroblasts (Ebert et al. 2002). ISVPs also can be formed extracellularly in the murine intestine or by treatment with intestinal proteases in vitro. During virion-to-ISVP conversion, σ3 is degraded and lost from virions, σ1 undergoes a conformational change, and μ1 is cleaved to form particle-associated fragments δ and ϕ (Figure 1). Removal of σ3 is thought to expose hydrophobic domains in μ1 that facilitate interactions of ISVPs with endosomal membranes, leading to delivery of core particles into the cytoplasm (Nibert et al. 1991; Liemann et al. 2002).

Transcription of the reovirus genome is fully conservative, i.e. both strands of the genome remain within the cores. The nature of the functional reovirus transcriptase is not fully understood. The λ1, λ2, λ3, and μ2 proteins all likely play important roles in viral RNA synthesis, with λ3 serving as the viral RdRp. Only positive-sense transcripts are produced during primary transcription, and these transcripts are capped, as the core contains virus-encoded capping enzymes. The λ2 protein has guanylyltransferase and methyltransferase activities (Luongo et al. 2000; Reinisch et al. 2000). Nascent transcripts leave the core via channels formed by pentamers of λ2 at the vertices of the fivefold symmetry axes. Transcripts are produced in a ratio according to their size; S-class RNAs are more abundant than M-class RNAs, which are in turn more abundant than L-class RNAs. Capped, full-length RNAs act as both mRNAs and templates for negative-strand RNA synthesis within progeny cores.

Replication of reovirus genomic dsRNA segments occurs within newly formed cores, although the mechanisms underlying this process are poorly understood. Plus-strand RNA is thought to be packaged during assembly of cores, where it serves as template for minus-strand synthesis. The assembly of the correct number of RNA segments into cores is highly regulated, but the process ensuring that each core receives a single copy of each RNA is unknown. Following synthesis of dsRNA, the nascent cores become transcriptionally active and enter a second round of mRNA synthesis. In contrast to the products of primary transcription, these secondary transcripts are not capped.

Both capped and uncapped RNAs serve as translational templates. There are different translation efficiencies of reovirus mRNAs, suggesting post-transcriptional control. The variability in translation is in part due to the sequence context of the initiator AUG (especially at the −3 and +4 positions) (Kozak 1981). The 3′-UTRs of some reovirus mRNAs also contain translational control sequences (Mochow-Grundy and Dermody 2001). During reovirus infection, most protein synthesis in the cell is viral in origin. Outer-capsid protein σ3 may play a central role in this process through its effects on the activity of the interferon-induced enzyme, protein kinase RNA (PKR). This effect is thought to relate to the affinity of σ3 for dsRNA and its capacity to compete with PKR for dsRNA binding (Imani and Jacobs 1988; Lloyd and Shatkin 1992; Schmechel et al. 1997). Sequestration of dsRNA by σ3 presumably attenuates PKR activation, thereby impeding the capacity of PKR to phosphorylate eIF-2a.

The morphogenesis of reovirus particles is complex. The earliest detectable newly formed particles contain single-stranded RNA (ssRNA). These particles, termed 'replicase particles,' are actively engaged in genomic dsRNA synthesis. Once dsRNA is synthesized, the replicase particles initiate secondary transcription and are termed 'transcriptase particles.' The additional uncapped transcripts lead to increased protein synthesis. Outer-capsid proteins condense onto the transcriptase particles, silencing transcription, to form mature, double-shelled reovirus virions. Viral nonstructural proteins are involved in collecting ssRNA prior to formation of replicase particles (Antczak and Joklik 1992) and may play additional roles in particle morphogenesis (Broering et al. 2000; Becker et al. 2001). A peculiar feature of reoviruses is the occurrence of oligonucleotides (di- to nonanucleotides) in viral particles. These RNA species appear to be synthesized following particle assembly and are likely to represent aborted products of transcription (5′ ends of mRNAs).

The mechanism by which progeny virions are released from infected cells has not been determined, but it is thought that reovirus egress occurs by cell lysis. However, most virus in infected cell lysates remains bound to cell fragments, which probably reflects the association of viral replication centers with cytoskeletal components. Reovirus induces apoptosis of infected cells. Thus, it is possible that virus may be released in association with membrane-bound apoptotic bodies.

Numerous attempts have been made to establish a reverse genetics system for reoviruses. Several reports describing such a system (e.g. Roner et al. 1990; Roner and Joklik 2001) await wider application.

Apoptosis induced by reovirus infection

Reovirus induces the morphological and biochemical hallmarks of apoptosis in cultured cells and in vivo. Strain-specific differences in the capacity of reovirus to induce apoptosis are determined by the σ1-encoding *S1* gene (Tyler et al. 1995). Binding of σ1 to both sialic acid (Connolly et al. 2001) and JAM1 (Barton et al. 2001b) is required to achieve maximal levels of apoptosis.

However, viral attachment is not sufficient to elicit an apoptotic response. Inhibitors of acid-dependent viral disassembly block apoptosis by reovirus (Connolly and Dermody 2002), indicating a requirement for post-attachment entry steps in apoptosis induction. Viral transcription, however, is dispensable for apoptosis by reovirus, as inhibitors of viral RNA synthesis do not diminish the capacity of reovirus to induce apoptosis (Tyler et al. 1995; Connolly and Dermody 2002). These findings suggest that apoptosis induced by reovirus is triggered by a signaling pathway initiated by early steps in the viral replication cycle.

A critical component of the signaling cascade that leads to apoptosis of reovirus-infected cells is the transcription factor NF-κB. Within hours following viral adsorption, reovirus activates NF-κB, and this activation is required to induce an apoptotic response (Connolly et al. 2000). In some cell types, reovirus infection leads to expression of death receptors DR4 and DR5 and their pro-apoptotic ligand TRAIL (Clarke et al. 2000), suggesting apoptosis is induced by an extrinsic cell-death pathway. However, mitochondrial injury during reovirus infection has been documented (Kominsky et al. 2002), providing evidence that intrinsic signals are also involved in apoptosis induced by reovirus infection.

Pathogenesis: the mouse model

The elucidation of viral genetic determinants of the pathogenesis of reovirus disease has led to the establishment of general principles of viral disease mechanisms (for reviews, see Virgin et al. 1997; Tyler 2001).

This analysis is based on two main observations:

- Different reovirus serotypes cause different disease manifestations in the CNS of newborn mice (reovirus type 1: hydrocephalus; reovirus type 3: encephalitis).
- Different reovirus serotypes have different RNA and protein migration profiles by polyacrylamide gel electrophoresis (PAGE) (Figure 3).

Because reovirus has a segmented genome, 'reassortant genetics' can be used to identify specific viral genes involved in various aspects of virus–host interaction. Parental virus strains that differ with respect to a given phenotype (e.g. tissue tropism) are used to generate progeny reassortant viruses containing different combinations of gene segments from each of the parents (Figure 4). Careful observation of mice infected with various reassortant viruses has revealed the relative contributions of individual genes or sets of genes and their products to the pathogenic process.

Viruses produce disease by interacting with the host in a discrete series of steps:

- entry into host
- primary replication
- spread through the host
- specific cell and tissue tropism
- host immune response.

Following oral inoculation, reovirus is taken up by Peyer's patches via the M cells (Wolf et al. 1981), specialized gut epithelia overlying the lymphoid tissue of the Peyer's patches. Virus then disseminates to various sites within the host including the CNS. However, not all reovirus strains are capable of growth in the intestine and systemic spread following oral inoculation. Strain T3D is neurovirulent after intracranial (Weiner et al. 1980b; Morrison et al. 1993) or intramuscular (Tyler et al. 1986) inoculation but does not infect the murine intestine after oral inoculation. By contrast, T1L produces high titers in intestinal tissue and spreads systemically (Rubin and Fields 1980; Keroack and Fields 1986; Bodkin and Fields 1989) (Table 2, p. 8).
Using T1L × T3D reassortant viruses, it was shown that the σ1-encoding *S1* gene and the λ2-encoding *L2* gene are the primary determinants of strain-specific differences in reovirus growth in the intestine (Bodkin and Fields 1989).

Following oral or intramuscular inoculation, strains of both serotypes invade the CNS, yet by different routes and with distinct pathological consequences (Table 2).
T1 reovirus spreads to the CNS hematogenously and infects ependymal cells (Weiner et al. 1980b; Tyler et al. 1986), resulting in hydrocephalus (Weiner et al. 1977). By contrast, T3 reovirus spreads to the CNS neurally and infects neurons (Weiner et al. 1980b; Tyler et al. 1986; Morrison et al. 1991), causing lethal encephalitis (Weiner et al. 1977; Tardieu et al. 1983). T1L × T3D reassortant viruses were used to show that the pathways of viral spread (Tyler et al. 1986) and tropism for neural tissues (Weiner et al. 1980b; Dichter and Weiner 1984) segregate with the σ1-encoding *S1* gene (Weiner et al. 1980a; Lee et al. 1981). Thus, σ1 determines the CNS cell types that serve as targets for reovirus infection.

Reovirus pathogenesis is not restricted to the CNS. Reovirus infection causes pathology and physiological dysfunction in a wide range of organs and tissues including the hepatobiliary system, myocardium, lungs, and endocrine tissues. Reovirus hepatobiliary disease (Wilson et al. 1994) and myocarditis (Sherry et al. 1989) in mice have become particularly well-established experimental models of viral injury at these sites.

Myocarditis induced by reovirus is unusual in comparison to other viral causes of myocarditis in that the pathogenesis is not immune-mediated. Instead, reovirus cytopathicity is a direct cause of myocyte injury, which results from a complex interplay of the interferon (Sherry et al. 1998; Noah et al. 1999; Azzam-Smoak et al. 2002) and apoptotic pathways (DeBiasi et al. 2001). Efficiency of viral RNA synthesis is a key factor in determining the extent of myocardial injury (Sherry et al. 1996). Accordingly, viral gene segments encoding proteins involved in

viral transcription and genome replication play important roles in determining strain-specific differences in the capacity of reovirus to induce myocarditis (Sherry and Fields 1989; Sherry and Blum 1994; Sherry et al. 1998).

Illness in humans

Reoviruses are recognized and well-studied pathogens of mice and other rodents, but it has been difficult to link reovirus infections to disease in humans. Although infections of humans are common, most infections are asymptomatic. Reovirus infections are occasionally associated with enteritis, rhinitis, and CNS disease in infants and children (Tyler 2001).

Reovirus has also been linked to neonatal biliary atresia in humans (Tyler et al. 1998). While a definitive causal relationship between reovirus infection and biliary atresia has not been established, it is quite provocative that infection of newborn mice (ND4 Swiss Webster) with a reovirus type 3 strain that utilizes sialic acid as a coreceptor was associated with viral replication in bile duct epithelium and abnormalities in hepatobiliary function very similar to those accompanying bile duct obstruction in humans, including hyperbilirubinemia, elevated levels of serum alkaline phosphatase, and steatorrhea (for details see Barton et al. 2003; for review Forrest and Dermody, 2003).

Epidemiology

By the end of childhood, most humans have antibodies against each of the three reovirus serotypes (Jackson

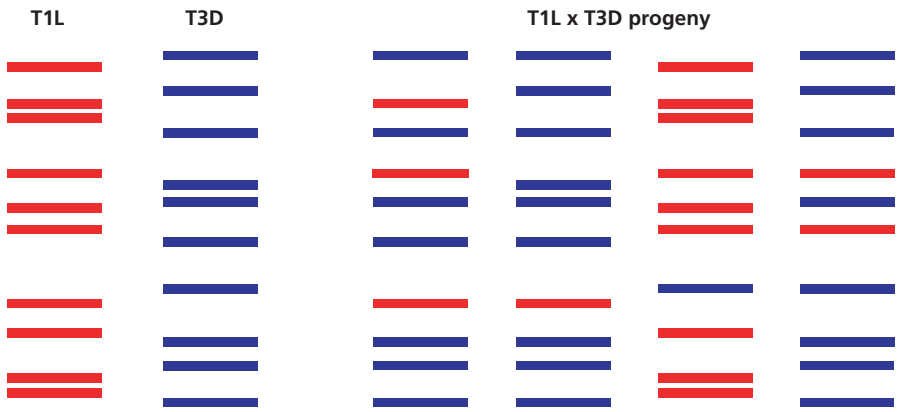

Figure 4 *Generation of reassortant viruses. Biological polymorphisms exhibited by different reovirus strains can be mapped to specific gene segments through the use of reassortant viruses. Reovirus strains are distinguishable by signature electrophoretic profiles of their dsRNA gene segments (i.e. electropherotypes). Co-infection of cells with different strains produces a collection of progeny reassortant viruses containing various combinations of gene segments from each parent. A phenotypic difference between two parental strains can be genetically mapped by screening the reassortant viruses in appropriate assays and correlating expression of the phenotype with a specific parental gene segment. The electropherotypes of prototype strains T1L and T3D are illustrated in this figure.*

Table 2 *Properties of reovirus pathogenesis attributable to σ1 protein*

	Functional property

Type 3	Variable[a]	Neural	Neurons	Sialic acid	JAM1

a) Some type 3 reovirus strains can infect the intestine and disseminate systemically. Others fail to infect intestinal tissue and do not spread to distant sites.

et al. 1961; Lerner et al. 1962; Leers and Rozee 1966). In a study conducted at a pediatric hospital in the USA, the incidence of anti-reovirus antibodies increased from less than 25 percent in those less than 1 year of age to greater than 70 percent in those over 3 years of age (Lerner et al. 1962). Reovirus-specific antibodies are also found in most mammals. Reovirus infections do not appear to have a seasonal distribution, although the original isolates were from patients with diarrheal illnesses occurring during the summer months. Reoviruses are commonly found in environmental water sources (Adams et al. 1982; Ridinger et al. 1982; Dahling et al. 1989), and it has been suggested that human fecal contamination is a major source of virus in water supplies (Matsuura et al. 1993).

Reovirus oncolysis

Transformed cells are substantially more permissive for reovirus infection than untransformed cells (Strong and Lee 1996). This property correlates with an activated *Ras* signaling pathway (Strong et al. 1998). Reovirus kills transformed cells in animals (Coffey et al. 1998) and is being investigated for the treatment of some forms of cancer in humans.

ORBIVIRUSES

Genome, gene protein assignment, and structure

The genome of orbiviruses consists of 10 segments of dsRNA of three size classes termed *L1–L3*, *M4–M6*, and *S7–S10*. Full-length sequences of each of the genome segments of BTV 10 have been determined (Roy 1989). Protein-coding assignments have been established for each of the BTV genes (Roy 2001). The genome segments, their size in bp, and the size, number of molecules, and location in the virion, post-translational modifications, and some of the recognized functions of the protein products are shown in Table 3.

With the exception of the *S10* RNA, orbivirus genes are monocistronic, encoding seven structural proteins (VP1–VP7) and four nonstructural proteins (NS1–NS3, NS3A). The 5′ and 3′ termini of the orbivirus RNA segments are conserved and have inverted complementarity (Roy 2001), theoretically allowing formation of 'panhandle' structures, a property common to other members of the *Reoviridae*.

The inner core of the virion consists of the segmented genome with which three minor proteins, VP1, VP4, and

Table 3 *Gene protein assignments and functions of orbivirus proteins (BTV 10)*

RNA segment		Protein				
Designation	Size (bp)	Designation	Deduced mol. mass (kDa)	Number of molecules per virion	Location in virion	Function (modification)
L1	3 954	VP1	149.6	12	Inner core	RdRp
L2	2 926	VP2	111.1	180	Outer capsid (exposed)	Viral attachment protein; hemagglutinin; type-specifying neutralization antigen
L3	2 772	VP3	103.3	120	Core (subcore layer)	Scaffold protein for VP7; interaction with genomic RNA
M4	2 011	VP4	76.4	ca. 24	Inner core	Guanylyltransferase; methyltransferases; NTPase; RNA 5′-triphosphatase; pyrophosphatase
M5	1 639	VP5	59.2	360	Outer capsid (under surface)	Glycoprotein; crossreactive antigen; not neutralization-specific; virus penetration; fusogenic; positioning of VP2?
M6	1 770	NS1	64.4	. . .	Nonstructural	Tubule formation; translocation of virus particles?
S7	1 156	VP7	38.5	780	Core surface	Group-specific antigen; core binding to insect cells
S8	1 124	NS2	41.0	. . .	Nonstructural	Phosphoprotein; binds ssRNA; morphogenesis (cytoplasmic inclusions)
S9	1 046	VP6	35.8	ca. 72	Inner core	Binds ssRNA and dsRNA; helicase; ATPase
S10	822	NS3	25.6	. . .	Nonstructural	Glycoprotein; virus release
	. . .	NS3A	24.0	. . .	Nonstructural	Function unknown

Slightly modified from Roy 2001, with permission of author and publisher.

VP6 (encoded by the *L1*, *M4*, and *S9* RNAs, respectively), are closely associated. These proteins serve as the viral RdRp, guanylyltransferase, and RNA-binding proteins, respectively. The inner core is surrounded by an inner capsid layer composed of VP3 trimers (interior of the inner capsid; encoded by the *L3* RNA), which form a scaffold for a layer of VP7 trimers (exterior of the inner capsid; encoded by the *S7* RNA). The structure containing the genome and proteins VP1, VP4, VP6, VP3, and VP7 is also referred to as the viral core. The core is surrounded by the outer capsid, which consists of VP5 (encoded by the *M5* RNA), a glycoprotein, and VP2 (encoded by the *L2* RNA). VP2 is the most variable of the BTV proteins and carries major epitopes determining serotype and neutralization specificity. VP2 is the orbivirus attachment protein and hemagglutinin (Roy 2001). Antibodies directed against VP2 protect animals from infection, but antibodies directed against VP5 do not.

There are four orbivirus nonstructural proteins:

- NS1 (encoded by the *M6* RNA)
- NS2 (encoded by the *S8* RNA)
- NS3/NS3A (encoded by the *S10* RNA, initiating from in-frame AUG codons and differing in size by 1.5 kDa).

The precise functions of the orbivirus nonstructural proteins are not fully understood (Roy 2001).

Although the three main genera of the *Reoviridae* (reo-, rota-, and orbiviruses) have unique characteristics in structure, replication, pathogenesis, and epidemiology, these viruses exhibit remarkable parallels in the functions of their structural proteins (Table 4). All these viruses have a virion-associated RdRp and proteins with RNA-capping activity. They also share structural proteins that act as scaffolds in several layers of the capsid and others that interact with receptors, hemagglutinate, and determine neutralization (serotype) specificity. There is increasing evidence that the nonstructural proteins have similar functions in morphogenesis, virion assembly, and release, but the parallels in the functions of these proteins are less obvious.

Replication

Orbiviruses are unusual among the *Reoviridae* in that they replicate in both mammalian and insect cells. This property reflects the capacity of these viruses to productively infect cells at very different temperatures (37°C and 22–27°C, respectively).

Table 4 *Functional similarities of structural proteins of* reovirus*, rotavirus, and* bluetongue virus[a]

		Protein designation (and coding RNA segment)					
Location in virion	**Function**	**Reovirus**		**Rotavirus**		**Bluetongue virus**	
Core (inner layer)	RdRp	λ3	(*L1*)	VP1	(1)	VP1	(*L1*)

Slightly modified from Mattion et al. 1994, with permission of authors and publisher.
a) Functional analogies of the nonstructural proteins (reovirus μNS, σNS, and σ1s; rotavirus: NS1–NS5; and bluetongue: NS1–NS3, NS3A) are difficult to define at present.
b) Depending on the strain, VP7, NSP2, and NSP3 are encoded by RNA 7, 8, or 9.

Orbiviruses attach via VP2 to sialic-acid-containing receptors on the surface of mammalian cells. It is possible that receptors in addition to sialic acid are used for viral attachment in a manner analogous to that of other members of the *Reoviridae*; however, such receptors have thus far not been identified. Core particles, which lack VP2 and VP5, adsorb well to and infect insect cells, suggesting that VP7 at the exterior of the core interacts with insect cell receptors. Virus enters mammalian cells by endocytosis, after which the outer capsid (VP2 and VP5) is removed. The resulting core particle is transcriptionally active and catalyzes synthesis of viral mRNAs. The viral RdRp has a temperature optimum in vitro of 28°C but retains activity at 37°C (Van Dijk and Huismans 1982), reflecting adaptation of viral replication to different types of host cells. VP4 mediates capping enzyme activities, resulting in the production of capped mRNAs (Martinez-Costas et al. 1998; Ramadevi et al. 1998; Ramadevi and Roy 1998). Viral proteins are synthesized from 2 to 14 hours after infection and accumulate in the cytoplasm. The viral NS1 protein forms extensive tubules throughout the cytoplasm, but their function is unknown (Eaton et al. 1990). Orbivirus release is thought to be accomplished by cell lysis.

Core-like particles (CLP) and virus-like particles (VLP) largely self-assemble when combinations of viral proteins (CLPs: VP3 and VP7; VLPs: VP2, VP3, VP5, and VP7) are overexpressed simultaneously in insect cells using baculovirus recombinants (French et al. 1990) (Figure 5).

Detailed morphological studies of VLPs (Hewat et al. 1994) and biochemical analyses of individual viral proteins have led to the identification of protein

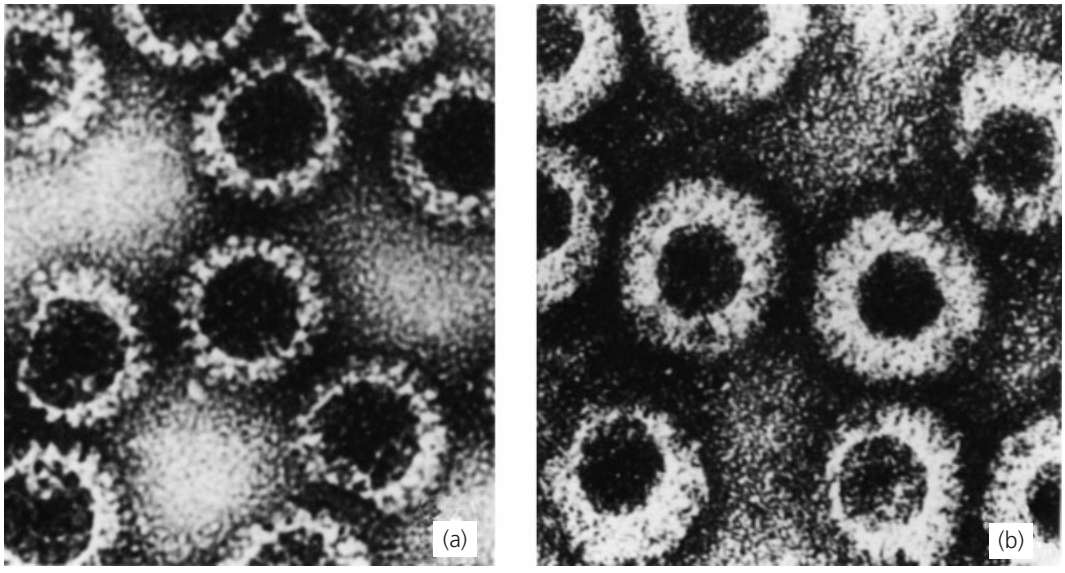

Figure 5 (a) *CLPs and* **(b)** *VLPs of BTV. The particles were obtained by coexpression of baculovirus recombinants in insect cells (CLPs: VP3 and VP7; VLPs: VP2, VP3, VP5, and VP7). Particles were purified and examined by cryo-electron microscopy and three-dimensional image reconstruction. (From French et al. 1990 with permission of the authors and publisher.)*

domains responsible for protein–protein and protein–RNA interactions (reviewed by Roy 2001). The structure of VP7 has been solved using X-ray crystallography, and its domain structure is known in atomic detail (Grimes et al. 1995). The structure of the BTV core also has been solved using X-ray crystallography, revealing significant insights into the nature of the enzymatic activities of the core and providing clues to mechanisms of RNA packaging (Grimes et al. 1998).

Pathogenesis

In mammals, BTV replicates mainly in the lymphoreticular system. The virus has a particular affinity for endothelial cells of capillaries, causing ischemic lesions, inflammatory changes, and edema. There is a prolonged viremia that lasts for up to 1 month, although neutralizing antibody appears 7–10 days following infection (Parsonson 1990). Different BTV serotypes are capable of gene segment reassortment in vitro and in their natural hosts (Samal et al. 1987), giving rise to considerable diversity among field isolates.

Illness

The incubation period for BTV-induced disease is 6–9 days. Illness starts with fever, followed by vomiting and hemorrhage. Bronchopneumonia occurs and can be fatal. Disease severity can vary, and many BTV infections are subclinical. Symptomatic disease is observed in 10–30 percent of infected animals, and mortality is approximately 5 percent (Parsonson 1990). Besides sheep, cattle are commonly infected, although these infections are usually asymptomatic. BTV can infect the fetus and is associated with abortions and fetal abnormalities in sheep and cattle (Parsonson 1990).

Epidemiology

BTV constitutes one of at least 14 serogroups of orbiviruses (Mertens et al. 2000) and occurs in 24 serotypes. These viruses infect sheep, cattle, goats, and wild ungulates in many countries of the tropical and subtropical zones (Parsonson 1990). Their distribution is supported by a variety of insect vectors (*Culicoides* midges, ticks, and mosquitoes) in which the virus replicates (Mellor 1990). Other orbivirus serogroups, such as African horse sickness virus (AHSV), occurring in horses, donkeys, and dogs, and epizootic hemorrhagic disease virus (EHDV), occurring in deer, also have diverged into serotypes. Sequence comparisons of BTV, AHSV, and EHDV indicate that there is considerable conservation of the *VP3* gene product (58–79 percent). There is less conservation of the *VP7* gene product (43–63 percent), the protein specifying the group antigen, and less still of the *VP2* gene product (32–45 percent), which specifies viral serotype (Roy 2001).

Vaccines

Antibodies specific for BTV VP2 are neutralizing and provide effective homotypic protection (Huismans et al. 1987). Generation of CLPs and VLPs by co-expression of viral genes in insect cells infected with baculovirus recombinants (e.g. French et al. 1990) (Figure 5) has enabled the development of vaccine candidates (Roy et al. 1992; Roy and Sutton 1998). These particles, formulated either as mixtures derived from different serotypes or as particle chimeras, have the potential to elicit broad protective immune responses. A vaccine of inactivated particles of AHSV serotype 4 has been shown to fully protect against homologous challenge (House 1998).

COLTIVIRUSES

Coltiviruses possess a genome of 12 segments of dsRNA and are now classified as a separate genus of the *Reoviridae* (Mertens et al. 2000). Within the *Coltivirus* genus, two groups and several subgroups have been defined based on sequence comparisons of RNA segments (Attoui et al. 1998). These viruses are isolated from ticks, mosquitoes, rodents, and humans. Colorado tick fever virus (CTFV) can cause a fatal disease in humans. Different isolates of CTFV differ mostly in RNA segments 4 and 6, suggesting that protein products of these genes are located in the outer capsid and carry neutralization-specific epitopes (Bodkin and Knudson 1987).

CTFV is endemic in the Rocky Mountain region of the USA and Canada. In the insect vector, which includes ticks of many species, CTFV infects the midgut, from which it spreads to other organs including the salivary glands, allowing transmission to mammalian hosts by bite. As rodents have prolonged CTFV viremia, they may serve as a reservoir for tick infection in nature. However, a variety of other mammals (e.g. marmots, deer, elk, and sheep) can also be infected. Humans are infected by bite but are not thought to generate sufficient viremia to maintain the transmission cycle (Monath and Guirakhoo 1996).

CTFV can be isolated from the erythrocytes of humans for as long as 120 days after infection, whereas it disappears from plasma very quickly (Bowen 1988). This cell-associated viremia is likely to originate from infection of bone marrow stem cells; from these cells, virus is continuously dispersed into the periphery in maturing erythrocytes. Interestingly, the viremia persists in the presence of a strong neutralizing antibody response (Monath and Guirakhoo 1996).

After an incubation period of 4 days (range 1–19 days), humans infected with CTFV develop fever (possibly due to elevated interferon levels), leukopenia, gastrointestinal symptoms (20 percent of cases), rash (10 percent), and meningoencephalitis (3–7 percent). A severe hemorrhagic form of the disease (purpura,

epistaxis, and gastrointestinal bleeding) is rarely seen. The case-fatality rate is less than 0.1 percent.

CTFV can be isolated from the blood of infected persons using continuous cell lines (e.g. Vero and BHK-21 cells), and viral antigen can be detected in erythrocytes by immunofluorescence testing (IFT). Serological diagnosis can be accomplished by IFT using infected Vero cells as antigen or by enzyme-linked immunosorbent assay (ELISA).

Treatment of Colorado tick fever is supportive. Ribavirin has been used in cases of severe hemorrhagic disease. However, controlled clinical trials to test its efficacy have not been reported.

Rotaviruses were discovered in 1973 as being associated with diarrheal disease in children (Bishop et al. 1973; Flewett et al. 1973) and have since been recognized as the major cause of gastroenteritis in infants and young children and in a wide range of animal species. In humans, they cause 500 000–600 000 deaths each year (Miller and McCann 2000), and there is an urgent need for a vaccine. For reviews of other viral causes of gastroenteritis, see Blacklow and Greenberg (1991), Kapikian (1994), Hart and Cunliffe (1997), Chiba et al. (1997), Desselberger (1998a), Chadwick and Goode (2001), Cohen et al. (2002), Desselberger and Gray (2003), and Adenovirus; Human enteric RNA viruses: astroviruses; and Human enteric RNA viruses: noroviruses and sapoviruses.

GENOME, GENE PROTEIN ASSIGNMENT, AND STRUCTURE

Rotaviruses have a genome of 11 segments of double-stranded RNA (dsRNA) which can be easily separated by polyacrylamide gel electrophoresis. The RNA segments code for six structural (VP1, VP2, VP3, VP4, VP6, VP7) and six nonstructural proteins (NSP1–NSP6) (Estes 2001). The structural proteins make up a triple-layered particle and are located in the core (inner layer; VP1–VP3), inner shell (intermediate layer; VP6) and outer shell (outer layer; VP4, VP7). The wheel-like (Latin: *rota*) appearance by electron microscopy of the triple-layered particles is diagnostic (Figure 1a). Figure 1b shows diagrammatically the gene coding assignment, the position of the structural proteins in the particles and their three-dimensional (3D) structure as obtained by image processing techniques from cryo-electron micrographs.

Further details of the 3D structure have been elucidated in a number of excellent studies by the groups of Prasad (Prasad et al. 1988, 1990, 1996; Shaw et al. 1993; Prasad and Chiu 1994; Lawton et al. 1997a, b, 1999, 2000; Prasad and Estes 1997; Crawford et al. 2001; Pesavento et al. 2001); Yeager (Yeager et al. 1990, 1994), Rey (Petitpas et al. 1998; Lepault et al. 2001; Mathieu et al. 2001) and Hewat (Thouvenin et al. 2001). According to their findings, the genome is comprised within the core shell formed by VP2. The transcription complex, consisting of VP1 and VP3, is attached at the 12 fivefold symmetry positions on the inside of the shell. The addition of VP6 (260 trimers) produces double-layered particles, and further addition of VP7 (780 molecules) and VP4 (60 dimers) leads to the formation of triple-layered particles which are the infectious virions after VP4 cleavage. The triple-layered capsid is ordered along five-, three-, and two-fold symmetry axes and is perforated by 132 aqueous channels of types I–III (located in the three symmetry positions). The type I channels play an important role in transcription (see below).

Complete gene–protein assignments have been achieved for several *Rotavirus* strains. Table 1, p. 3

Table 1 *Genes, gene protein assignments, and functions of proteins of group A* Rotavirus

RNA segment		Protein product					
No.	Size (bp)	Description	Deduced mol. mass (kDa)	Location	No. of molecules per virion	Post-translational modification	Functions
1	3 302	VP1	125.0	Inner core	12	–	RNA-dependent RNA polymerase; binds ssRNA; complex with VP3
2	2 690	VP2	94.0	Core	120	Myristylation	Binds RNA; required for replicase activity of VP1
3	2 591	VP3	88.0	Inner core	12	–	Guanylyltransferase; methyltransferase; complex with VP1
4	2 362	VP4	86.8	Outer capsid (dimer)	120	Proteolytic cleavage to VP5* and VP8*	Hemagglutinin; cell attachment; neutralization antigen (ab protective); fusogenic; protease-enhanced infectivity; virulence (mice, piglets)
5	1 611	NS53, NSP1 (VP5)	58.7	Nonstructural	NA[c]	–	Binds RNA; virulence (mice); nonessential for replication (some strains); interacts with IRF-3
6	1 356	VP6	44.8	Inner capsid (trimer)	780	Myristylation	Group- and subgroup-specific antigen; protection (intracellular neutralization)? Required for transcription
7[a]	1 059	VP9 (NSP3)	34.6	Nonstructural (dimer)	NA	–	Binds RNA (3′ end); competes with cellular PABP for interaction with eIF-4G1 (translation); inhibits host-cell translation
8[a]	1 104	NS35, NSP2 (VP8)	36.7	Nonstructural (octamer)	NA	–	Binds RNA; NTPase; helicase; involved in +strand RNA packaging; virulence (mice)
9[a]	1 062	VP7	37.4[b]	Outer capsid (trimer)	780	Cleavage of signal sequence; glycosylation	Neutralization antigen (ab protective); binds Ca^{2+}
10	751	VP12 (NSP4)	20.3	Nonstructural	NA	Glycosylation (VP10, NS28); trimming	Intracellular receptor (morphogenesis); viral enterotoxin (secreted cleavage product); protection by specific ab; virulence (mice, piglets)
11	667	VP11 (NSP5)	21.7	Nonstructural	NA	O-glycosylation, phosphorylation	Binds RNA; protein kinase; interacts with NSP2, VP2, and NSP6
		NSP6	12.0	Nonstructural	NA		Interacts with NSP5

Modified from Estes (2001).

a) This gene protein assignment is of the SA11 rotavirus strain.

b) Second in-frame initiation codon located 30 codons downstream (deduced mol. mass 33.9 kDa).

c) NA, not applicable.

lists the RNA segments and their products for the simian rotavirus SA11 strain; also noted are post-translational modifications and functions as far as known.

CLASSIFICATION INTO SUBGROUPS, SEROTYPES, AND GENOTYPES

A classification of rotaviruses has been derived from immunological characteristics of various components of the particles and from genomic composition (Estes 2001). Groups A–E can be differentiated according to lack of serological crossreactivities of the inner capsid protein VP6 with polyclonal and monoclonal antibodies. There may be two more groups, F and G (Bridger 1987). Within group A rotaviruses, subgroups (I, II, I+II, nonI, nonII) were defined according to exclusive reactivities of two VP6-specific monoclonal antibodies (Greenberg et al. 1982). Types within group A are determined by cross-neutralization studies as serotypes (Offit et al. 1986; Green and Kapikian 1992) or by sequence comparison as genotypes. (Typing of rotaviruses within other groups is rudimentary.) As the two surface proteins (VP4 and VP7) carry neutralization-specific antigens, a dual classification scheme, similar to that developed for influenza viruses, has been established, differentiating G types (for VP7 which is a **g**lycoprotein) and P types (for VP4 which is a **p**rotease-sensitive protein, being cleaved post-translationally into its subunits VP5* and VP8*). So far, 14 G types and at least 20 P types have been differentiated, indicating extensive genomic diversity within group A rotaviruses (Estes 2001). As these proteins are coded for by different RNA segments and as rotaviruses of the same group reassort readily in doubly infected cells, both in vitro (Garbarg-Chenon et al. 1984; Graham et al. 1987) and in vivo (Gombold and Ramig 1986; Ward et al. 1990), the observed diversity resulting from various combinations of VP7 and VP4 types is very large. Whilst the correlation of G serotypes and genotypes is practically complete, for many P genotypes no serotype has been established yet. Therefore P serotype and genotype are designated separately but jointly (where available), the latter in square brackets: for example, the human Wa strain is classified as G1P1A[8], the human DS-1 strain as G2P1B[4], the equine strain Eq/L338 as G13P12[18], the bovine strain Bo/993/83 as G7P[17], etc.

REPLICATION

Rotaviruses spread via the oral–fecal route and infect the small intestine after oral ingestion. Multiplication occurs in the mature epithelial cells at the tips of the villi of the small intestine. Rotaviruses grow well in secondary monkey kidney cells and in immortalized monkey kidney cell lines (MA104, BS-C1) in the presence of trypsin, and therefore their replication in vitro could be studied in detail (Estes 2001). Figure 2 is a diagrammatic presentation of these events. Triple-layered particles (i.e. the infectious virions) attach to the host cells via the outer-layer protein VP4 (Ludert et al. 1996). Virus entry is by receptor-mediated endocytosis or direct penetration (Cuadras et al. 1997; Gilbert et al. 1997). The cellular receptor or receptors have not been fully characterized yet, but some animal strains use sialic acid located on glycolipids (Ciarlet and Estes 1999; Ciarlet et al. 2002b). Other strains seem to recognize galactose (Jolly et al. 2001). In addition to glycolipids, several integrins have been proposed to mediate uptake, possibly in a post-attachment step, acting as co-receptors (Coulson et al. 1997; Guerrero et al. 2000; Hewish et al. 2000). The heat-shock cognate (Hsc) protein 70 may also be involved as a co-receptor (Guerrero et al. 2002). For porcine rotavirus, a ganglioside receptor has been described (Rolsma et al. 1998). Replication is exclusively in the cytoplasm. After removal of the outer capsid proteins, the viral RNA-dependent RNA polymerase (coded for by RNA 1) is activated in double-layered particles (Cohen et al. 1979), and by use of the VP1/VP2/VP3 transcription complex (Lawton et al. 2000) large numbers of positive-strand RNA molecules are transcribed and exit from the double-layered particles via their 12 aqueous channels located on the vertices of the fivefold symmetry axes. This process is ATP-dependent. Transcription is asymmetric, i.e. only positive-strand RNAs appear as transcription products. Multiple RNA molecules can be transcribed from a single actively transcribing particle. The new RNA molecules act as mRNAs, and their translation products start to accumulate in the cytoplasm. NSP3 is intimately involved in translation by binding to the 3′ end of mRNA and to the eukaryotic translation factor eIF-4G (Vende et al. 2000). Molecules of mRNA seem to be pulled through VP2 oligomers (the nascent core) by means of a complex formation with NSP2 which has NTPase activity and acts as a molecular motor (Taraporewala et al. 1999; Patton 2001; Schuck et al. 2001; Taraporewala and Patton 2001). NSP5 that interacts with VP2 and NSP2 (Berois et al. 2003) is also involved at this stage. Double-layered particles are formed, consisting of VP1, VP2, VP3, and VP6 and several of the nonstructural proteins, and containing one genome equivalent of packaged single-stranded RNA which is then replicated to form dsRNA. Double-layered particles accumulate and form pseudocrystalline aggregates termed viroplasm (= intracytoplasmic inclusion bodies). It is not clear at present how the very tight packaging control of rotaviruses (and of other *Reoviridae*) is achieved. When budding through the rough endoplasmic reticulum (RER), whereby NSP4 acts as an intracellular receptor for VP6, double-layered particles incorporate VP7 and VP4 to form the third, outer layer (a transient, RER-derived envelope is shed before complete maturation). Triple-layered infectious virions are released by cell lysis. VP4 may reach the plasma membrane through

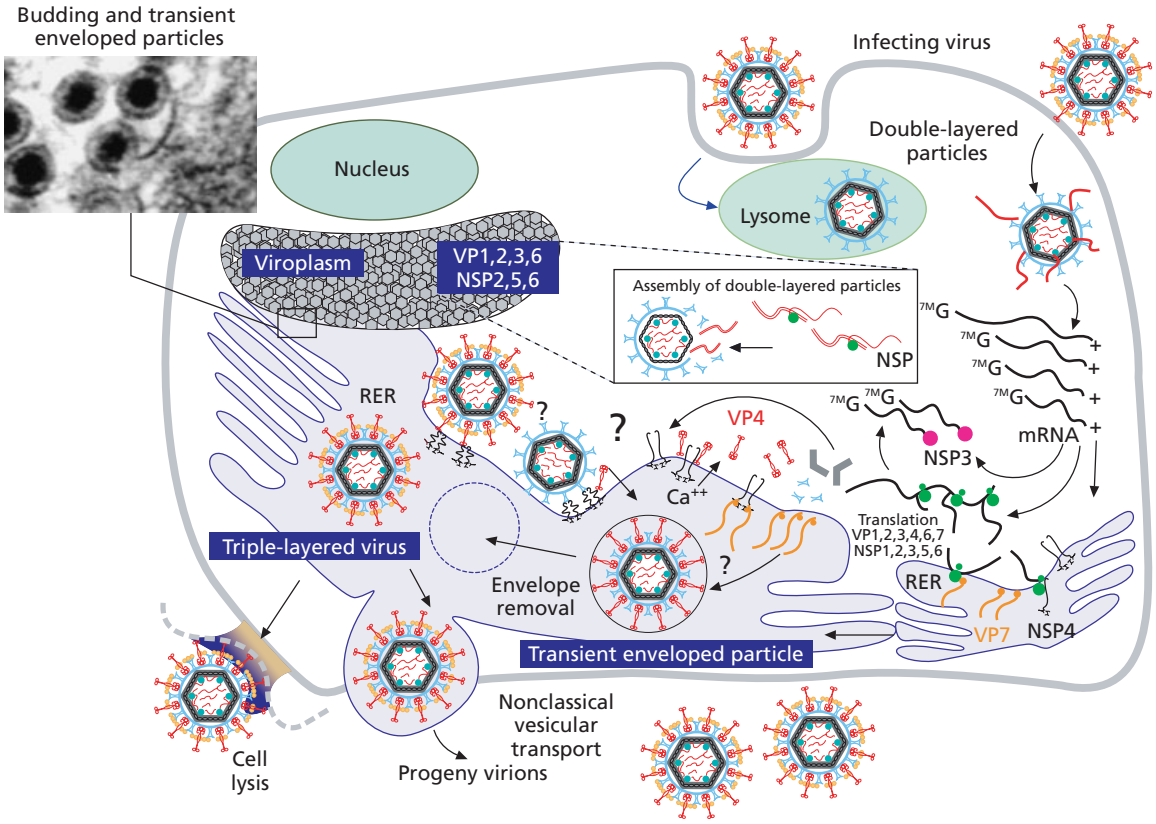

Figure 2 *Major features of the* Rotavirus *replication cycle. For details see text. Triple layered rotavirus particles (TLPs, i.e. infectious virions) attach to the surface of the host cell by its outer layer protein, VP4, interacting with sialic acid (in glycolipids) or other receptors on the cell surface. Virus entry is by receptor mediated endocytosis. The outer layer proteins VP4 and VP7 are removed (possibly in lysosomes). The resulting double layered particles (DLPs) are transcription active, i.e. they synthesize and extrude large numbers of mRNAs (specific for all RNA segments) that are capped but not polyadenylated. Only positive sense transcription products are made. The mRNAs are translated into proteins using the cellular machinery. This process is facilitated by the viral NSP3 interacting with the 3′ end of the mRNA and forming a complex with the eukaryotic translation factor eIF4G. Rotavirus cores are formed, consisting of VP2, VP1, and VP3, into which rotavirus mRNA molecules are incorporated. The rotavirus proteins NSP2 and NSP5 are intimately involved in this process which is ATP dependent. Within the cores the ssRNA segments are replicated to form the dsRNA genome. The early packaging process is tightly controlled. Rotavirus cores interact with VP6 to form DLPs which in turn aggregate into pseudocrystalline arrays termed 'viroplasm' (i.e. intracytoplasmic inclusion bodies). DLPs then bud through the rough endoplasmic reticulum (RER); this step is facilitated by interaction of NSP4 that has become part of the RER membranes with DLPs via VP6 (NSP4 acting as an intracellular receptor for DLPs). In the RER, DLPs acquire VP7 and VP4 to become TLPs. During this process particles are transiently enveloped; however, the envelope is shed before complete maturation (this step is a unique characteristic of rotavirus replication that is still poorly understood). TLPs are then released by the cell undergoing lysis or by a 'non-classical' vesicular transport involving interaction with lipid 'rafts' near the plasma membrane. (Redrawn from Estes 2001, with permission of the publisher)*

the microtubule network and interact with cholesterol liposphingolipid rafts, possibly promoting assembly near the plasma membrane (Nejmeddine et al. 2000; Sapin et al., 2002; not shown in Figure 2) (For further details of structure–function correlations and replication see Prasad and Estes 1997; Lawton et al. 2000; Estes 2001). In immunodeficient hosts and under certain experimental conditions, rotaviruses undergo genome rearrangements (for review: Desselberger 1996).

PATHOGENESIS: ANIMAL MODELS

Cell death and desquamation reduce digestion and adsorption of nutrients (primary malabsorption) and lead to villous atrophy. This is followed by a reactive crypt-cell hyperplasia accompanied by increased secretion, which is thought to contribute to the severity of diarrhea. The local pathogenesis is shown diagrammatically in Figure 3.

Several animal models for rotavirus infections are being explored (mice, rabbits, piglets, rats; Saif et al. 1994; Burns et al. 1995; Conner and Ramig 1996; Guérin-Danan et al. 1998; Ciarlet et al. 2002a). Of those, piglets and rats are infectable with human strains and produce diarrhea; they are therefore of particular interest. Many features of rotavirus infections, particularly pathogenicity and immune responses, have been studied in animal models to a greater extent than in man (see below).

The viral factors determining pathogenicity of rotaviruses have been investigated in several animal models

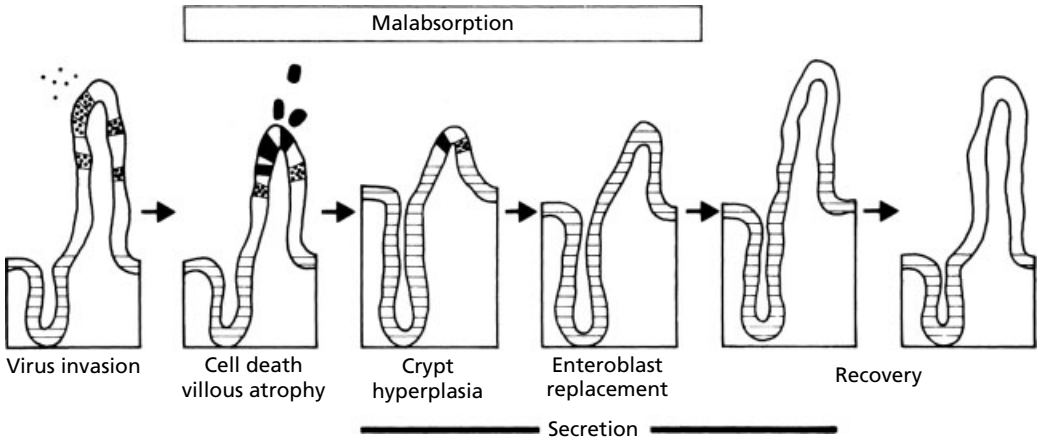

Figure 3 Rotavirus *pathogenesis (diagram). Development of damage to gut mucosa and ensuing diarrhea. (Redrawn from Phillips 1989, with permission of the author and publisher.)*

(piglets, mice, rabbits). The product of RNA segment 4, VP4, is likely to be a major determinant (Offit et al. 1986; Gorziglia et al. 1988; Bridger et al. 1992, 1998; Burke et al. 1994a, b), but products of other structural genes (RNA 3 coding for VP3 and RNAs 8 or 9 coding for VP7) and nonstructural genes (RNA 5, coding for NSP1, RNA 8 coding for NSP2, and RNA 10 coding for NSP4) have also been associated with pathogenicity (Table 2) (Broome et al. 1993; Hoshino et al. 1993, 1995; Ball et al. 1996 ; review by Burke and Desselberger 1996).

The discovery of NSP4 as an enterotoxin (Tian et al. 1994, 1995; Ball et al. 1996) has allowed the old observation that rotavirus-infected animals exhibit profuse diarrhea prior to the detection of histological lesions to be explained. NSP4 or a peptide thereof (aa 114–135) induce dose- and age-dependent diarrhea in laboratory animals (mice, rats) in the absence of histological changes (Ball et al. 1996) (Figure 4).

NSP4 produces an increase in intracellular Ca^{2+} concentration (Tian et al. 1994), disturbing the cellular homeostasis. Recently it was found that a peptide of NSP4, that is active as an enterotoxin is secreted from infected cells (Zhang and Zeng 2000) and is able to induce intracellular Ca^{2+} elevation and diarrhea in mice. It is thought that the secreted protein binds to a (still hypothetical) receptor and thus affects uninfected cells (Zhang and Zeng 2000; Tafazoli et al. 2001). A model of the NSP4 action is proposed in Figure 5, p. 8.

Antibody to NSP4 has been shown to reduce the severity of diarrheal disease in suckling mice (Estes 2003). The effect of rotavirus infection on the enteric nervous system also may play a role in pathogenesis (Lundgren et al. 2000).

ILLNESS AND TREATMENT

After a short incubation period of 24–48 hours, the onset of illness is sudden with watery diarrhea, vomiting, and rapid dehydration. Untreated rotavirus infection is a major cause of infant death in the developing world. It should be noted, though, that the clinical symptoms of rotavirus infection may vary widely: asymptomatic infections of neonates with so-called nursery strains have been described (Hoshino et al. 1985; Gorziglia et al. 1988), but also central nervous system infections (Iturriza-Gómara et al. 2002a) and chronic infections and hepatitis in children with immunodeficiencies (Gilger et al. 1992).

Table 2 Rotavirus *genes implicated in pathogenicity in different hosts*

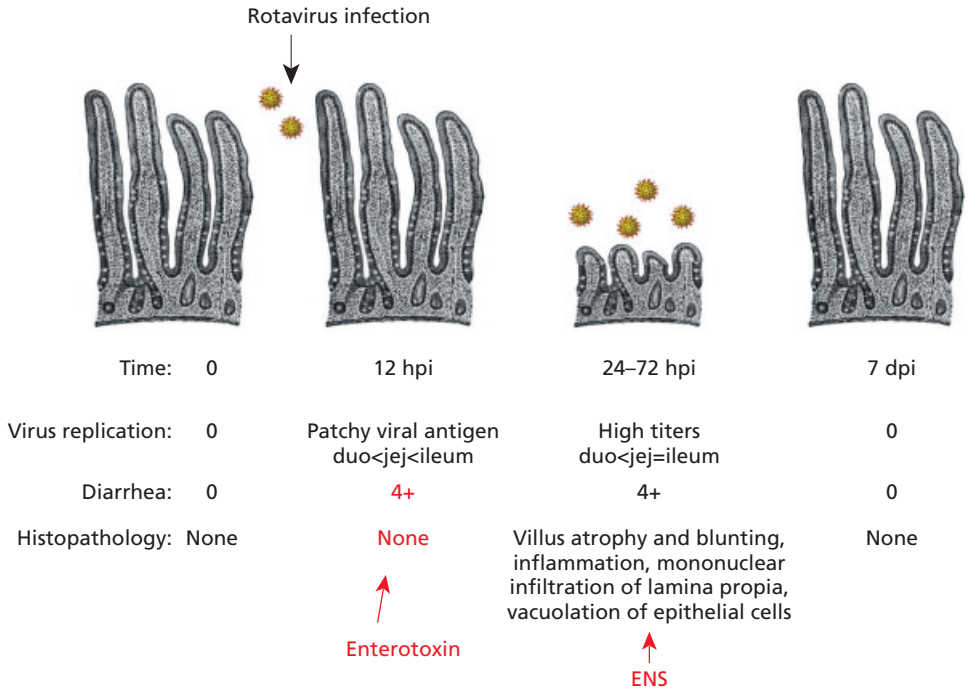

Figure 4 Rotavirus *pathogenesis. Correlation of virus replication, histopathology, and disease over time. Enterotoxin, NSP4; ENS, enteric nervous system. (From Estes 2001 with permission of the publisher)*

Treatment is by oral, subcutaneous, or intravenous rehydration (Bhan et al. 1994; International Study Group on Reduced-osmolarity ORS Solutions 1995; Desselberger 1999). Table 3 gives the WHO-approved formulae of oral rehydration solutions (ORS). There is no approved specific antiviral treatment (Desselberger 1999). Oral immunoglobulins seem to shorten the period of virus shedding and diarrhea but are not in routine therapeutic use (Guarino et al. 1994; Bass 2003).

DIAGNOSIS

The number of virus particles in the gut at the peak of the diarrhea can be as high at 10^{11}/ml of feces. Diagnosis is therefore relatively easy using electron microscopy, enzyme-linked immunosorbent assays (ELISA) or passive particle agglutination techniques.

Electron microscopy allows quick identification of the pathognomonic double- and triple-layered rotavirus particles. These particles differ morphologically from other viruses causing acute gastroenteritis: enteric adenoviruses, human caliciviruses (noro- and sapo-viruses), astroviruses, and small round viruses (SRV) (Doane 1994) (see Adenovirus; Human enteric RNA viruses: astroviruses; and Human enteric RNA viruses: noroviruses and sapoviruses).

Serological assays to detect rotavirus antigen are used widely, mostly applying direct or indirect ELISAs. The tests can be calibrated and quantified and are easily performed. If the detecting anti-rotavirus antibody is type-specific, the test can be used for G and P typing; this, however, depends on the presence of triple-layered virus particles in the clinical specimen. Another frequently used rapid technique is a passive particle agglutination test (Ruggeri et al. 1992). Details of procedures are described by Yolken and Wilde (1994).

The viral genome can be detected easily after phenol extraction of RNA from crude or semipurified rotavirus-containing specimens and separation by polyacrylamide gel electrophoresis (PAGE) followed by silver staining (Herring et al. 1982). Nowadays, the procedure is of value mainly in outbreak investigations.

The use of rotavirus-specific oligonucleotide primers in reverse transcription-polymerase chain reactions (RT-PCR) has allowed not only sensitive detection but also subgroup determination and typing for both G and P types when the subgroup- and type-specifying sequence diversities are exploited (Gouvea et al. 1990; Gentsch et al. 1992; Iturriza-Gómara et al. 2002c, 2003b). For rotavirus typing, RT-PCR has become the method of choice (Iturriza-Gómara et al. 1999, 2000).

Human rotaviruses can be grown in vitro on monkey kidney cells in the presence of trypsin (Ward et al. 1984), but the procedure is not in routine use.

IMMUNE RESPONSE AND CORRELATES OF PROTECTION

After neonatal or primary rotavirus infection a mainly serotype-specific humoral immune response is elicited, but there is also partial protection against subsequent

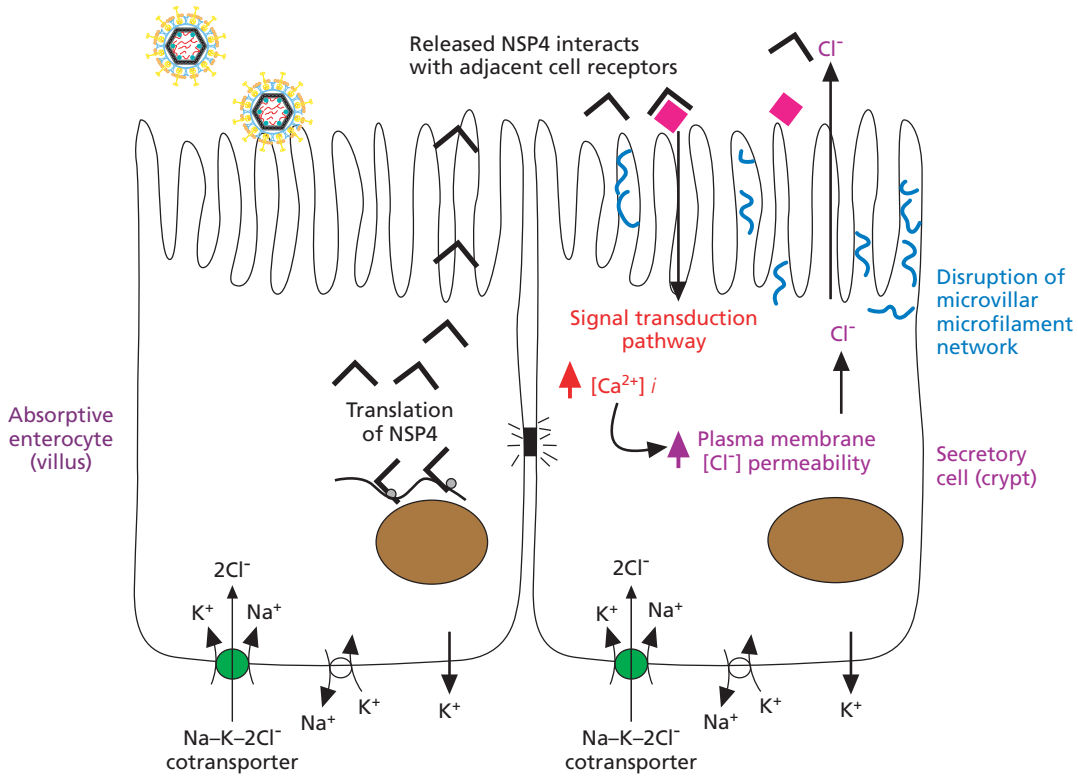

Figure 5 *Proposed model of NSP4 action.* Rotavirus*-infected enterocytes produce virus-specific proteins including NSP4. NSP4 is released from cells by lysis or secretion, and this extracellular NSP4 acts in a paracellular fashion by binding to an as yet unidentified receptor for NSP4 on adjacent cells. This triggers a rapid response involving a signal transduction pathway that mobilizes intracellular Ca^{2+} and results in increased plasma membrane Cl^- permeability. The secretory cells are likely to be crypt cells but might also be villus enterocytes. The plasma membrane permeability is age-dependent, based on studies in CFTR knock-out mice (Morris et al. 1999). Extracellular NSP4 also causes a delayed disruption of the organization of filamentous actin and transepithelial resistance (Tafazoli et al. 2001). ∧, NSP4; ◆, (putative) NSP4 receptor. (Redrawn from Estes et al. 2001)*

heterotypic infections (Bishop et al. 1983; Chiba et al. 1986; Friedman et al. 1988). The exact correlates of protection remain to be determined (Offit 1994), but the best are provided by coproantibodies of the IgA subclass (Coulson et al. 1992; Matson et al. 1993; Feng et al. 1994, 1997; Yuan et al. 1996; To et al. 1998) although not in all cases (O'Neal et al. 2000). There seems to be protection from severe disease after natural infection and vaccination (see below) even if the serotype of the challenging virus differs from that of the first infection or vaccination (Ward et al. 1992; Offit 1994; Velazquez et al. 1996). In the mouse model, homologous protection from infection depends on the level of mucosal IgA antibodies; heterologous protection can also be achieved, but depends on dose and strain and also seems to be correlated with the ability of the heterologous strain to stimulate detectable rotavirus-specific intestinal IgA antibody (Feng et al. 1994, 1997). In mice, rotavirus VP6-specific IgA monoclonal antibodies that lack direct neutralizing activity can protect from primary infection. It has been proposed that the mechanism of protection is by intracellular viral inactivation following transcytosis of IgA (Burns et al. 1996; Herrmann et al. 1996; Feng et al. 1997; Schwartz-Cornil et al. 2002) as experimentally shown for influenza viruses (Mazanec et al. 1995), but firm data on 'intracellular neutralization' have not become available so far for rotaviruses. The extent to which heterotypic protection is efficient in humans remains unclear (Offit 1994). There are rotavirus-specific cytotoxic T-cell responses but their exact role in overcoming the infection and protecting against subsequent infections is not clear (Offit et al. 1993; Offit 1994; Franco and Greenberg 1995).

EPIDEMIOLOGY

The epidemiology of group A rotavirus infections is complex, as at any one time and in any geographical location rotaviruses of different G types co-circulate (e.g. Noel et al. 1991; Gentsch et al. 1996; Ramachandran et al. 1998). The relative incidence of G types also changes over time in the same location. Approximately 95 percent of co-circulating strains are types G1–G4 in most places, typically G1P1A[8], G2P1B[4], G3P1A[8], and G4P1A[8], but other G types may be represented at high frequencies, particularly in tropical areas (Gentsch et al. 1996; Leite et al. 1996; Ramachandran et al. 1996; Cunliffe et al. 1999; Iturriza-Gómara et al. 2000; for review: Desselberger et al. 2001). Recently, G9 rotaviruses have been isolated as one of the predominant outbreak strains in several locations in the USA (Ramachandran et al. 1998) and in the UK (Iturriza-Gómara et al. 2002b). Group B rotaviruses have caused outbreaks of diarrhea in children and adults in China (for review see Hung 1988; Fang et al. 1989) and have been isolated from sporadic cases of gastroenteritis in Calcutta, India (Krishnan et al. 1999; Kobayashi et al. 2001). Group C rotaviruses are associated with small outbreaks in humans (Caul et al. 1990; Jiang et al. 1995).

Besides the accumulation of point mutations (genomic drift; Iturriza-Gómara et al. 2003b), gene reassortment upon dual infection with co-circulating human, or human and animal strains (genomic shift; Iturriza-Gómara et al. 2001, 2003b) is likely to play a major role in generating the increasing diversity of rotaviruses. Although reassortment of two different viruses with 11 gene segments theoretically predicts 2^{11} different progeny viruses (including the parent strains), constraints to reassortment have been identified in naturally circulating rotaviruses (Graham et al. 1987). The genes encoding the structural proteins VP6, VP7, and VP4 reassort independently, although some constraints among the genetic lineages of these proteins seem to exist (Iturriza-Gómara et al. 2001, 2003b). By contrast, the genes encoding VP4 and NSP4 are inextricably linked in progeny, possibly through their intense interaction during morphogenesis (Iturriza-Gómara et al. 2003a).

As for group A rotaviruses (Estes 2001), there is a large animal reservoir for group B rotaviruses. Whilst transmission of animal rotaviruses to man has been demonstrated, it is not clear at present to what extent animal rotaviruses can be transmitted to man (Das et al. 1993; Gentsch et al. 1996).

VACCINE DEVELOPMENT

Rotavirus infections have been recognized as a major viral infection in children worldwide (Bern and Glass 1994), and therefore development of vaccine candidates has been a major goal and has been in progress since the early 1980s. Results have been mixed for some time, owing to the enormous genomic and antigenic diversity of rotaviruses (for review see Kapikian 1994; Vesikari 1994; Desselberger 1998b). Mainly animal rotaviruses (of simian or bovine origin) have been used as live attenuated vaccines. In many cases, protection from infection and/or mild disease was only modest (40–50 percent). By contrast, 70–80 percent protection from severe disease including dehydration was recently achieved (Rennels et al. 1996; Joensuu et al. 1997; Pérez-Schael et al. 1997), particularly when applying a cocktail of viruses, for example as a tetravalent vaccine containing a rhesus monkey rotavirus (RRV) of G3 type and three monoreassortants, individually carrying the *VP7* gene of human serotypes G1, G2, and G4 in the RRV genetic background. A tetravalent RRV-based reassortant vaccine (Rotashield®) received Food and Drug Administration (FDA) approval as a universal vaccine in the USA in August 1998, and recommendations for its usage have been issued (Centers for Disease Control and Prevention 1999a). More than 1.5 million doses were administered in the following 10 months. During that time cases of intussusception were observed in vaccinees, particularly within 3–7 days after the first dose with a relative risk of 27.9 (95 percent confidence interval 10.8–72.1; Murphy et al. 2001), and attributable risks of between one case of intussusception in every 4 700–9 500 children vaccinated (Murphy et al. 2001) and one case in 11 000 children vaccinated (Kramarz et al. 2001) have been calculated. These observations led the Centers for Disease Control and Prevention (CDC) and the American Academy of Pediatrics to withdraw the recommendation for use in infants (Centers for Disease Control and Prevention, 1999b, c). Recent ecological studies have failed to demonstrate an increase in the incidence of intussusception during the time of usage of the Rotashield vaccine (Chang et al. 2001; Simonsen et al. 2001), suggesting that the attributable risk may be even smaller.

However, due to the urgent need for a rotavirus vaccine, the research for its development is ongoing. There are several other live attenuated candidate vaccine strains: the bovine WC3 virus (G6P7[5]) and G1 and P1A[8] reassortants thereof (Treanor et al. 1995; Clark et al. 1996), the attenuated human strain 89-12 (G1P1A[8]: Bernstein et al. 1998, 1999), and multivalent vaccines comprising representative strains carrying G1–G4 and G9. Two live, attenuated oral rotavirus candidate vaccines, consisting of a) a pentavalent WC3-based, human reassortant vaccine (RotaTeq™), and b) a monovalent strain 89-12-based vaccine (Rotarix™), are in advanced stages of large phase III trials (Heaton 2004, De Vos 2004), and are likely to enter the licensure process in 2005. Rotarix™ has already been approved in Mexico in early 2005.

In addition, new approaches to immunization are under investigation: applying inactivated virus or synthetic peptides (Conner et al. 1993), enhancing rotavirus immunogenicity by microencapsidation (Offit et al. 1994), using virus-like particles (VLP) obtained by co-expression of viral proteins (VP2, VP4, VP6, and VP7) from baculovirus recombinants in insect cells (Crawford et al. 1994; Conner et al. 1996; O'Neal et al. 1997; Ciarlet et al. 1998) or using DNA vaccines (Herrmann et al. 1996; Chen et al. 1997, 1998). Expression of rotavirus proteins in plants (potatoes, bananas) from vectors downstream of plant-specific promoters is also under investigation ('edible vaccines,' Arntzen 1997; Yu and Langridge 2001; Mason et al. 2002). In view of the heterotypic immune responses observed after natural infection and immunization, it must be determined which of the epidemiologically important human P and G rotaviruses are mainly required for protection (Offit 1994).

Rubella

JENNIFER M. BEST, SAMANTHA COORAY, AND JANGU E. BANATVALA

Historical introduction	1	Laboratory diagnosis	20
Properties of the virus	1	Prevention	23
Antigenic composition	9	References	27
Clinical and pathological aspects	10		

HISTORICAL INTRODUCTION

Rubella was first described in the mid-eighteenth century by two German physicians, de Bergen and Orlow. At that time it was frequently known by the German name 'Röteln,' and it was due to the early interest of the German physicians and the general acceptance of a German name that the disease subsequently became known as 'German measles.' For many years, German measles was frequently confused with measles and scarlet fever, other infectious diseases presenting with rash, and at one time was considered to be a cross between them. The clinical differences between these diseases were recognized in the nineteenth century and rubella was accepted as a distinct disease by an International Congress of Medicine in London in 1881 (Smith 1881). The disease received comparatively little attention, for infection was generally mild and severe complications were rare, until the 1940s when the association between maternal infection and such congenital defects as cataract, heart disease, and hearing loss was first recognized (Gregg 1941). This report is discussed in more detail later.

Rubella virus (RUBV) was not isolated in cell culture until 1962, when Parkman and colleagues (1962) detected the presence of RUBV in primary vervet monkey kidney cell cultures by means of the interference technique and Weller and Neva (1962) reported unique cytopathic effects in primary amnion cell cultures. Tests for neutralizing and hemagglutination inhibition (HAI) antibodies were reported in 1962 (Parkman et al. 1962, 1964) and 1967 (Stewart et al. 1967) respectively. These tests allowed seroepidemiological investigations to be conducted. The fine structure of RUBV was not determined until 1968 as it is difficult to obtain the high titers of virus required for electron microscopy (Best et al. 1967; Holmes et al. 1968). Much of the work on the molecular structure and replication of RUBV was carried out in the late 1980s and early 1990s, some time after similar work on other viruses. This was probably because RUBV is slow to grow in cell culture, high levels of virus are difficult to produce consistently and the high G+C content of the genome made sequencing difficult.

PROPERTIES OF THE VIRUS

Classification

Rubella virus, an enveloped single-stranded RNA virus, belongs to the family *Togaviridae* (Togaviruses) and is probably distantly related to the alphaviruses (Frey 1994). Unlike other togaviruses, RUBV has no known invertebrate host and has been placed by itself in the genus *Rubivirus*.

Morphology and structure

The virion has a mean diameter of 58 nm with a 30 nm core (Figure 1) (Best et al. 1967; Holmes et al. 1968; Murphy et al. 1968). The core is surrounded by a lipoprotein envelope with surface spikes 5–8 nm in length. In thin sections of infected cells an electron-lucent zone is seen between the core and the envelope. The virion is

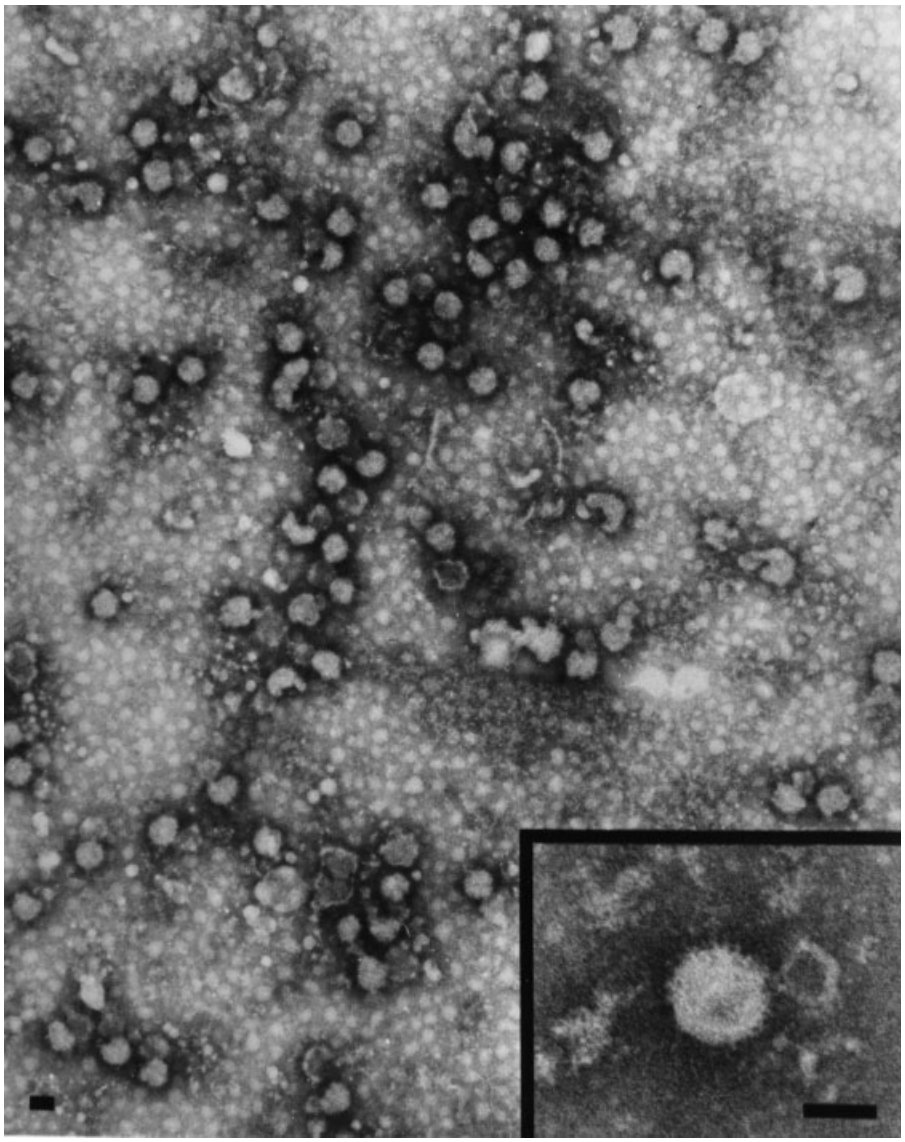

Figure 1 *Negatively stained preparation of rubella virus. Inset, an enlarged particle, showing spikes. Bar, 50 nm (kindly provided by Dr. I. Chrystie).*

pleomorphic, owing to the delicate nonrigid nature of the envelope. The symmetry of the nucleocapsid has been difficult to establish because of its instability, but rotational analysis of thin sections of rubella virions suggests that the core has a T = 3 icosahedral symmetry and 32 capsomers (Matsumoto and Higashi 1974).

Physical properties of RUBV are shown in Table 1 and were reviewed by Horzinek (1973, 1981). The stability of the virus is enhanced by the addition of proteins and $MgSO_4$ to the suspending medium. Because of the lipid content of the viral envelope, RUBV is inactivated by detergents and organic solvents. The effects of these and other chemicals have been reviewed (Parkman et al. 1964; Norrby 1969; Plotkin 1969; Horzinek 1973, 1981; Herrmann 1979).

Genome organization

The RUBV genome consists of a single strand of positive sense RNA, 9 762 nucleotides (nt) in length, which is capped at the 5′ end and polyadenylated at the 3′ end. The cap is required for efficient translation as it serves as a ribosome recognition site (Oker-Blom 1984; Frey 1994). The genome contains two nonoverlapping open reading frames (ORF) separated by a linker region of 123 nucleotides (nt) in the same translation frame. The 5′ proximal ORF extends from nt 41 to 6 388 and encodes the p200 polyprotein precursor for the nonstructural proteins (NSP) p150 and p90 (Dominguez et al. 1990; Pugachev et al. 1997a; Liang and Gillam 2000). The 3′ proximal ORF extends from nt 6 512 to 9 700, and encodes the structural proteins (SP): capsid (C), and

$TCID_{50}$, 50% tissue culture infective dose.

glycoproteins E1 and E2 (Dominguez et al. 1990; Frey 1994; Yao et al. 1998). The gene order is 5′-p150–p90–C–E2–E1-3′ (Forng and Frey 1995). The genomic RNA serves as the template for synthesis of a complementary negative-sense RNA strand, which in turn, is the template for synthesis of positive-sense 40S genomic and 24S subgenomic RNA, from which the SPs are translated (Figure 2).

The base composition of the genome is 14.9 percent A, 15.4 percent U, 30.8 percent G and 38.7 percent C, making the G+C composition 69.5 percent, the highest reported for an RNA virus. This initially made sequence determination difficult, and errors were made in the first sequences reported (Dominguez et al. 1990). Genome-length cDNA clones have been produced and used to synthesize infectious RNA transcripts (Wang et al. 1994).

Virus life cycle

ATTACHMENT AND ENTRY

RUBV can replicate in a variety of cell lines which suggests that the receptor for RUBV is a ubiquitous molecule (reviewed by Frey 1994). The receptor has not yet been identified, but as membrane lipid molecules play an essential role it may be a lipid–carbohydrate complex (Mastromarino et al. 1990). The reproductive life cycle of RUBV takes place in the cytoplasm. Like most enveloped animal viruses, RUBV probably enters cells by receptor-mediated endocytosis and uses endocytic machinery to travel within the cytoplasm (Sodeik 2000). During endocytosis, the virion is internalized in a coated vesicle, which is transported to the endosomal compartment. The low pH environment of the endosome triggers a conformational change in the envelope glycoproteins that favors the fusion of viral and endosomal membranes (Katow and Sugiura 1988; reviewed by Frey 1994). The low pH also causes the C protein to undergo a structural change which makes it more hydrophobic, and allows uncoating of nucleocapsid to occur (Mauracher et al. 1991; Lee and Bowden 2000). Both events suggest that the low pH environment mediates delivery of viral genomic RNA into the cytoplasm.

REPLICATION, TRANSCRIPTION, AND TRANSLATION

The replication cycle of RUBV in vertebrate cell cultures is slow and less efficient than that of alphaviruses. Peak virus production usually occurs at 48 h postinfection (Hemphill et al. 1988; Frey 1994). Replication of RUBV has been suggested to occur in ‘replication complexes’ that appear as membrane-bound cytoplasmic vacuoles, lined internally with vesicles and associated with the rough endoplasmic reticulum (RER). The vesicles within the complex appear to be the sites of viral replication, and may also protect the genomic RNA from cellular ribonucleases. The replication complexes also appear to serve as sites for nucleocapsid assembly (Lee et al. 1994; Lee and Bowden 2000). Some RUBV replication complexes are modified lysosomes, characterized by the presence of degenerating material within the vacuole. However, others may be endosomal in origin, as observed in alphavirus-infected cells (Togaviruses) (Magliano et al. 1998).

Following the uncoating of capsid and release of genomic RNA into the cytoplasm, the 40S genomic RNA serves as the template for nonstructural protein (NSP) synthesis. The NSPs are translated from the 5′ proximal ORF as a 2 116 amino acid polyprotein, p200 (200 kDa), which is proteolytically cleaved to produce two nonstructural proteins p150 (residues 1–1 301, 150 kDa) and p90 (residues 1 302–2 116, 90 kDa) (Marr et al. 1994; Forng and Frey 1995; Chen et al. 1996). Preceding the NSP-ORF there are three potential AUG start sites at nucleotides 3, 41, and 57. Translation of the NSP-ORF is initiated at AUG_{41}, whereas AUG_3 and AUG_{57} are in a different reading frame and terminate at nucleotides 54 and 90, respectively. Neither of these short ORFs are essential for virus replication (Pugachev et al. 1997a; Pugachev and Frey 1998a).

The cleavage of the p200 polyprotein precursor is mediated by an RUBV-encoded protease within the C-terminal region of p150, which is homologous to several other viral and cellular papain-like proteases (Gorbalenya et al. 1991; Marr et al. 1994). The catalytic dyad is formed by residues Cys-1152 and His-1273 and cleavage takes place at Gly-1301 in the sequence Gly_{1300}–Gly_{1301}–Gly_{1302} (Marr et al. 1994; Chen et al. 1996; Liang and Gillam 2000). Site-directed mutagenesis of Gly-1301 to Ala or Val, and of Gly-1300/1302 to Val abrogates cleavage and results in non-infectious virus (Chen et al. 1996; Liang and Gillam 2000).

The 40S positive-sense genomic RNA also acts as the template for the synthesis of a complementary negative-sense strand of RNA. The negative strand, which is present in double-stranded form, is in turn the template for synthesis of the positive-sense 40S genomic RNA and 24S subgenomic RNA. p200 is the principal RNA-dependent RNA polymerase (RdRp) for negative-strand RNA synthesis, and cleavage products p150/p90 are required for positive-strand (genomic and subgenomic) RNA synthesis (Liang and Gillam 2000, 2001). Thus the switch from the synthesis of negative to positive-strand RNA is regulated by NSP processing. The p150 protein has also been shown to be localized in RUBV replication complexes (Kujala et al. 1999). Negative strand RNA synthesis continues to accumulate until 10 h postinfection, and remains constant thereafter. Synthesis of positive-strand RNAs (genomic and subgenomic) begins 10 h postinfection and escalates dramatically. This replication pattern resembles that of alphaviruses where negative-strand synthesis ceases after 4–6 h and switches to positive-strand RNA synthesis (Sawicki et al. 1981; Liang and Gillam 2001).

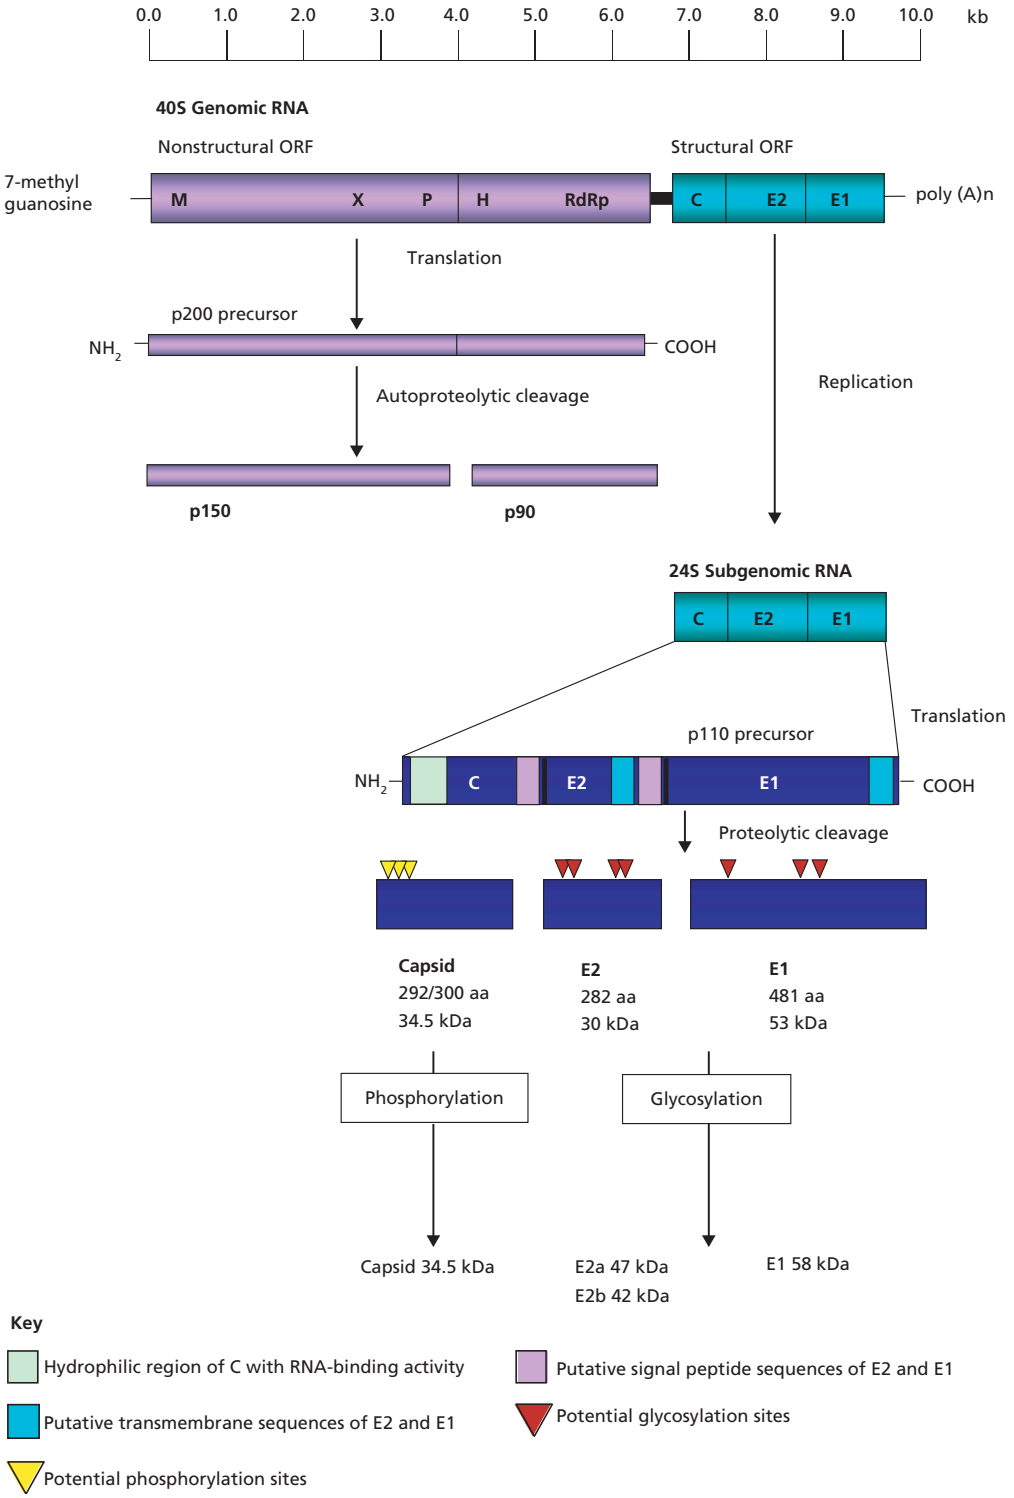

Figure 2 *Schematic representation of the steps involved in the replication translation, and processing of Rubella virus structural and nonstructural proteins. The RUBV genome consists of two long nonoverlapping ORFs, the 5′ ORF encodes the nonstructural proteins and the 3′ ORF encodes the structural proteins. The translation of RUBV RNA produces the p200 precursor, which is cleaved to produce the p150 and p90 nonstructural proteins. This initiates the synthesis of the full-length negative-strand RNA. The negative strand acts as a template for the synthesis of the full-length positive strand RNA for new viral progeny and the 24S subgenomic RNA. The 24S subgenomic RNA is translated into the p110 polyprotein precursor, which is proteolytically cleaved and post-translationally modified to produce the structural proteins C, E2, and E1. Within the 5′ nonstructural ORF are putative amino acid sequence motifs for methyltransferase (M), RNA-dependent RNA polymerase (RdRp), helicase (H), and papain-like cysteine protease (P) activity. The X motif indicates a region of unknown function, which has homology to alphaviruses, hepatitis E virus, and coronaviruses.*

The subgenomic RNA is translated to produce a 1 063 amino acid polyprotein precursor, p110 (110 kDa), which is proteolytically cleaved to produce the SPs C, E2, and E1 (Figure 2) (Kalkkinen et al. 1984; Oker-Blom 1984). The cleavage of p110 is thought to occur at signal peptide sequences that precede the amino termini of E2 and E1. The E2 and E1 signal peptides remain attached to the carboxy termini of C and E2, respectively, and direct the insertion of these proteins into the endoplasmic reticulum (ER) (Suomalainen et al. 1990; Marr et al. 1991; Baron et al. 1992). The capsid protein lacks the autoprotease activity of other alphavirus C proteins and cleavage of p110 is mediated by a host-cell signalase found within the lumen of the ER (Clarke et al. 1988; Frey and Marr 1988; Oker-Blom et al. 1990). The E2 signal peptide is required for RUBV glycoprotein-dependent localization of capsid to the juxtanuclear region and subsequent virus assembly in the golgi (Frey 1994; Qiu et al. 1994; Law et al. 2001). Retention of the E2 signal peptide on the carboxy terminus of capsid is unique to Rubella virus within the *Togaviridae* (Law et al. 2001).

Following proteolytic cleavage E1 and E2 form disulfide-linked heterodimers before they exit the ER. Heterodimerisation of E1 with E2 is required for E1 to be correctly folded and transported from the ER to the Golgi and the cell surface. Incorrectly folded proteins are retained in the ER (Frey 1994). An internal hydrophobic domain in E1 (aa 81–109) plays a major role in the formation of the E1–E2 heterodimer (Yang et al. 1998). The capsid protein forms dilsulfide linked homodimers (Waxham and Wolinsky 1983; Baron and Forsell 1991). Newly synthesized 40S genomic RNA is packaged with the RUBV capsid protein to form nucleocapsids. A 29 nt sequence (nt 347–375), within the genomic RNA has been identified as a binding domain for capsid, and a peptide region (amino acids 28–56) with specific RNA binding activity has been identified in the capsid (Liu et al. 1996; Wolinsky 1996).

DEFECTIVE INTERFERING (DI) RNAS

Serial undiluted passage of RUBV in Vero cells results in the production of DI RNAs, approximately 7 000 and 800 nt in length (Frey and Hemphill 1988). Characterization of these DI RNAs revealed that the 7 000-nt species contained a 2 500–2 700-nt deletion in the SP-ORF, and the 800 nt species was the subgenomic DI RNA synthesized from the larger species (Derdyn and Frey 1995). These are the only types of DI RNA which are continuously generated. Although DI RNAs are generated during persistent infection, their presence is not necessary to establish persistence (Frey and Hemphill 1988).

VIRUS RELEASE

Newly synthesized RUBV particles are released by budding from both the plasma membrane and internal membranes. The nucleocapsid core buds from the modified internal membranes and subsequently attains E1 and E2 glycoproteins and the host-cell lipids it requires to form the viral envelope. The mechanism by which the nucleocapsid interacts with E2–E1 heterodimers and the precise mechanism of budding is not known. However, E1 transmembrane and cytoplasmic domains have been found to be important in the late stages of virus assembly. The cytoplasmic domain of E1 may interact with the capsid protein to drive the budding process (Yao and Gillam 1999; Lee and Bowden 2000).

In vitro, virus release varies according to the type of cells infected. Vero cells release more virus into the cell culture medium than BHK-21 cells, as virus maturation only occurs at the plasma membrane and less intracellular virus is produced (Bardeletti et al. 1979). In BHK-21 virus maturation occurs both at the plasma membrane and at the Golgi and vacuoles of the cytoplasm. Wolinsky (1996) suggested that the capacity to mature within intracellular vacuoles, avoiding the host's immune system, may enable the virus to establish persistent infections in humans. Pathak et al. (1994), using immunoelectron microscopy, reported spherules (pleomorphic membrane-bound structures containing a dense thread-like structure) as well as virions budding from the surface of infected Vero cells.

EFFECT ON THE HOST CELL AND ULTRASTRUCTURAL STUDIES

RUBV infection in Vero cells does not affect total cellular RNA synthesis, and total cell protein synthesis is only modestly inhibited (Hemphill et al. 1988). However, this effect may be cell-type dependent as, in contrast, others have reported an increase in cellular metabolism (Vaheri and Cristofalo 1967; Bardeletti 1977).

In RUBV-infected cell cultures, virus-producing cells display intracellular membrane alterations and vacuolation approximately 2 days after infection. Membrane alterations included proliferation and distension, as well as the appearance of crystalline inclusions and annulate lamellae (Bardeletti et al. 1979; Pathak et al. 1994). Freeze-substitution electron microscopy of RUBV-infected cells has revealed the presence of homogeneously dense particles lacking a virus core within Golgi stacks, which coexist with mature virions, and appear to be virion precursors (Risco et al. 2003).

Large osmiophilic inclusion bodies containing myelin whorls and densely packed vesicles of varying size have been observed in the epithelial cells of human fetal nasal and tracheal organ cultures infected in vitro with RUBV (Kistler et al. 1967). The cytoplasmic ground substance as well as the extracellular space in close vicinity to the microvilli of these cells contained numerous viruslike particles with a diameter of 380–700 Å. It is possible that the inclusion bodies described by these authors correspond to the replication complexes analyzed by Lee and Bowden (2000).

RUBELLA VIRUS-INDUCED APOPTOSIS

RUBV-induced cytopathic effect has been shown to be due to caspase-dependent apoptosis in a number of susceptible cell lines (Pugachev and Frey 1998b; Megyeri et al. 1999; Hofmann et al. 1999; Duncan et al. 1999; Cooray et al. 2003; Domegan and Atkins 2002). Replicating virus is required for the induction of apoptotic cell signaling, which begins early post-infection (Megyeri et al. 1999; Cooray et al. 2003). The genetic determinants of cytopathogenicity have been mapped to the NSP-ORF (Pugachev et al. 1997b), but these have not been demonstrated to be directly involved in RUBV-induced apoptosis. Expression of the capsid protein alone was shown to induce cell death in transfected RK13 cells (Duncan et al. 2000). However, this function of the RUBV capsid is disputed by Hofmann et al. (1999), who demonstrated that expression of the entire SP-ORF reading frame did not cause apoptosis. Whether RUBV-induced apoptosis is dependent upon p53 is uncertain. Although p53 and p21 protein expression, and *p21* gene expression is detected in RUBV-infected Vero cells (Megyeri et al. 1999), p53 null neurons die in the same way as normal neurons in response to RUBV infection (Domegan and Atkins 2002). Anti-apoptotic protein Bcl-X is able to confer partial protection against RUBV infection in BHK-21 cells, but not in RK13 cells (Duncan et al. 1999).

REGULATORY ELEMENTS

The Rubella virus genome contains four regions of nucleotide sequence, which are thought to function as regulatory signals for RUBV replication, and have homology to the alphavirus genome (Dominguez et al. 1990; Frey 1994). Two of these regions are located at the 5′ and 3′ termini of the RUBV genomic RNA and are predicted to form stable stem-loop (SL) structures, and are termed the 5′ (+) SL and 3′ (+) SL, respectively. The 5′ (+) SL is located between nucleotides 15 and 65, it is preceded by a 14-nt single-stranded leader (ss-leader) sequence and consists of a terminal loop and a hinge region. A complementary equivalent of the 5′ (+) SL is present at the 3′ end of the viral minus-strand RNA (termed the 3′(−) SL), and is thought to serve as a promotor for initiation of positive-strand genomic RNA by the viral replicase (Pugachev and Frey 1998a). The 3′ (+) terminal 305 nt of the RUBV genome is predicted to form four stable SL structures. The first two SLs (SL1 and SL2) are located at the end of the the E1 coding region, and the second two (SL3 and SL4) within the 59-nt 3′ untranslated region (UTR) that precedes the poly(A) tract. An inverted repeat sequence of 12 nt preceding the 59-nt 3′ UTR and capable of forming a SL structure, is required for initiation of negative-strand synthesis (Nakhasi et al. 1990, 1994).

Pogue et al. (1993) analyzed the transcriptional activity of the 5′ and 3′ ends of the genome by constructing chimeras of chloramphenicol acetyl transferase (CAT) RNA flanked by the 3′(+) or 5′(+) SL sequences. The translational efficiencies of the 5′(+) and 3′(+) SLs were measured by the level of CAT activity from the chimeras in transfected cells. Both 3′ and 5′(+) SLs were found to be necessary for efficient translation of CAT RNA in vitro and in vivo.

The third region of homology consists of 23 nucleotides upstream of the subgenomic (SG) RNA start site (nt −46 to −23). This site has been termed the SG promoter and synthesis of SG RNA is initiated in this region on a negative-strand copy of the genomic RNA (Frey 1994; Tzeng and Frey 2002). In contrast, the SG promoter region of alphaviruses is immediately adjacent to the RNA start site. The region necessary for synthesis of RUBV SG RNA and production of viable virus has been mapped to −28 nt upstream (5′) through to at least +6 nt downstream (3′) of the SG start site (Tzeng and Frey 2002). The predicted secondary structure around the SG promoter region consists of two stem-loop structures SLI (−20 to −47 nt) and SLII (−16 to SG start site). However only SLII lies within SG promoter region and may be necessary for promoter function (Tzeng and Frey 2002).

A fourth predicted regulatory region lies 224 nt downstream of the 5′ end and consists of a stretch of 46 nt. However, unlike alphaviruses, this region does not form a predicted double stem-loop configuration, and its functional significance is unknown.

INTERACTION OF THE RUBV GENOME WITH CELLULAR PROTEINS

Cellular host factors are often involved in RNA virus replication and translation. Cellular proteins with RNA recognition elements may contribute enzymatic, structural, and regulatory activities required for RNA synthesis. A number of cellular proteins have been identified which interact with the RUBV genome.

The SL at the 3′ (+) end of the genome is able to bind to three host-encoded cytosolic proteins (61, 63, and 68 kDa). Phosphorylation of the host proteins is necessary for this interaction (Nakhasi et al. 1990). The 61 kDa protein has been purified and identified as the simian homolog of human calreticulin (Singh et al. 1994; Nakhasi et al. 1994). Phosphorylation of calreticulin is required for RNA-binding activity and calreticulin autophosphorylates itself at Ser and Thr residues. RNA binding and autophosphorylation activities were localized to the N-terminal 180 amino acids (aa). RNA binding activity was abrogated by deletion of the first ten aa residues, whereas autophosphorylation activity was localized to aa 60–180 (Singh et al. 1994; Atreya et al. 1995). The specific binding of calreticulin to the 3′(+) is important in regulating RUBV RNA negative strand synthesis.

UV cross-linking and RNA gel shift assays were used to identify host-cell proteins which interacted with the 5′

(+) SL. Two host proteins (53 and 59 kDa) present in both RUBV infected and uninfected cells were found to interact specifically with the 5′ (+) SL. Human serum with anti-Ro/SS-A antigen specificity immunoprecipitated the 53 and 59 kDa protein-RNA complexes containing the 5′ (+) SL RNA (Pogue et al. 1993). Serum from individuals with various immune disorders, which recognized La, or Ro and La autoantigens, immunoprecipitated ribonucleoprotein complexes containing both the 3′ and 5′ (+) SL RNAs. Like Ro, the La autoantigen was found to interact specifically with the 5′ (+) SL (Pogue et al. 1996). Identification of autoantigens binding to RUBV RNA suggests they may play a role in replication and pathogenesis.

Polypeptides

The SP ORF has two closely spaced AUG initiation codons, which may both be used indiscriminantly to produce capsid protein of 292 or 300 aa in length (Clarke et al. 1988). The capsid protein is phosphorylated, nonglycosylated, and has a molecular weight of 33 kDa. The protein is highly basic due to a high proportion of proline and arginine residues, which probably contribute to dimerization and binding of the 40S genomic RNA within the viral nucleocapsid. RUBV capsid protein is phosphorylated prior to virus assembly (Garbutt et al. 1999). A number of Ser/Thr residues within the capsid are potential phosphorylation sites, but site-directed mutagenesis experiments identified Ser 46, within the RNA binding region, as the most significant (Law et al. 2003). Capsid phophorylation is not essential for virus replication, but mutation of Ser 46 to Ala impairs virus growth and cytopathic effect. Hyperphosphorylated capsid mutants bind viral RNA more efficiently than wildtype capsid, and phosphatase treatment of wildtype improved RNA binding. This suggests that the capsid undergoes a dephosphorylation step prior to interaction with genomic RNA and nucleocapsid assembly (Law et al. 2003).

Host-cell mitochondrial protein p32 has been shown to bind to the N-terminal capsid domain and may regulate nucleocapsid assembly (Garbutt et al. 1999; Mohan et al. 2002). The exact physiological function of p32 is unknown, although it was originally identified as a C1q binding protein, it is capable of binding to a wide range of cellular and viral proteins (Beatch and Hobman 2000; Mohan et al. 2002). Binding of capsid to p32 at the mitochondria and overexpression of the SPs, results in clustering of the mitochondria to the perinuclear region.

E2 is 282 aa in length, and in most RUBV strains sequenced, it contains four potential *N*-linked glycosylation sites (Asn-X-Ser/Thr/Cys), where X can be any residue except proline. E2 also contains *O*-linked carbohydrates (Lundstrom et al. 1991). More than two forms of E2 occur (42–47 kDa) which differ in their degree of glycosylation (Bowden and Westaway 1985; Waxham and Wolinsky 1985).

E1 is 481 aa in length, has a molecular weight of 58 kDa, and three potential *N*-linked glycosylation sites (Figure 2) (Kalkkinen et al. 1984; Bowden and Westaway 1985; Waxham and Wolinsky 1985). E2–E1 heterodimers are membrane-bound and exposed on the surface of the virus particle. E2 is less accessible to the action of enzymes and antibodies than E1, suggesting that E2 is buried under E1 in the E2–E1 heterodimer (Waxham and Wolinsky 1985).

The RUBV structural proteins have been expressed in *Escherichia coli* and mammalian cells using Sindbis virus and vaccinia virus vectors, and in insect cells using baculovirus-expression vectors. Recombinant proteins have been purified from all of these systems (Seppanen et al. 1991; Londesborough et al. 1992; Oker-Blom et al. 1995; Chen et al. 1995; Orellana et al. 1999; Johansson et al. 1996). E1 and E2 have been expressed in soluble form (Hobman et al. 1994c; Seto et al. 1995), and virus-like particles containing the three structural proteins have been produced in transient and stably transfected CHO and BHK-21 cells (Hobman et al. 1994a, 1994b; Qiu et al. 1994).

RUBV NSPs contain a number of motifs of functional significance (Figure 2). P150 contains a region of homology to alphavirus NSP3, termed the X-motif, which is located adjacent to the protease domain, between aa 834 and 940. This motif has only been found in the genomes of the alphaviruses, Rubella virus, Hepatitis E virus, and possibly coronaviruses (Dominguez et al. 1990; Gorbalenya et al. 1991; Frey 1994). The X motif is necessary for *trans* cleavage activity of the NSP protease, but the exact function is still unknown. It is speculated that the proline-rich region within the X-motif may provide a protein–protein interaction domain that enables protease to easily gain access to its *trans* substrate (Liang and Gillam 2000). A methyltransferase (MT) motif has been identified at the N-terminus of p150 (Rozanov et al. 1992). It consists of a hydrophobic segment followed by a glycine-rich loop and is believed to have a role in the capping of viral RNA (Koonin 1993).

The second NSP, p90, contains two global amino acid motifs, which are conserved among positive-sense RNA viruses: a GDD motif (aa 1 966–1 968) indicative of RdRp activity, and a GKS/T motif indicative of helicase activity (Dominguez et al. 1990; Frey 1994; Pugachev et al. 1997a). Mutation of either Asp-1967 or Asp-1968 residues to Ala within the GDD motif are lethal. Mutation of Gly-1966 to Ala blocks virus replication and impairs infectivity, demonstrating that RUBV does have RdRp catalytic activity (Wang and Gillam 2001). This supports the role of p90 in positive-strand RNA synthesis.

ANTIGENIC COMPOSITION

Antigenic properties

Only one serotype of rubella virus has been described, and the virus is serologically distinct from other togaviruses. Early work on RUBV identified hemagglutinating (HA), complement-fixing (CF), precipitating (Le Bouvier 1969) and platelet-aggregating (PA) (Penttinen and Myllyla 1968) antigens. Kobayashi (1978) demonstrated that RUBV also has hemolytic activity.

The HA activity is associated with the surface projections on the viral envelope. It can be obtained from the supernatant fluid of infected BHK-21 cell cultures if these are maintained on serum-free medium or if nonspecific inhibitors of hemagglutination (serum lipoproteins) are first removed by kaolin treatment from the serum included in the maintenance medium (Stewart et al. 1967). Alternatively, treatment of the RUBV harvest with EDTA will separate HA from nonspecific inhibitors by removing Ca^{2+} (Furukawa et al. 1967). Rubella HA can also be prepared by alkaline extraction of infected BHK-21 or Vero cell cultures (Halonen et al. 1967). Although treatment of virus with ether destroys the HA activity, treatment with ether and Tween 80 retains this activity and increases the titer of the antigen, because of the formation of subunits. Ca^{2+} is required for the attachment of HA to erythrocytes. Optimum conditions for hemagglutination and further details of the nonspecific inhibitors of HA and methods for their removal from test sera were reviewed by Herrmann (1979).

Three CF antigens have been described: (1) a large particle antigen with a density of 1.19–1.23 g/ml in sucrose gradients and associated with the infectivity and HA activity; (2) a small particle ('soluble') antigen, which is probably a subunit of the protein coat of the virus (Schmidt and Styk 1968); and (3) a 150S particle, which appears to be associated with the ribonucleoprotein core of the virus (Vesikari 1972). High-titer preparations of RUBV can be used as CF antigens. These are usually prepared either by concentration of infected cell culture fluids or by alkaline extraction of infected cells (Herrmann 1979). BHK-21 and Vero cells are used for the production of suitable high-titer virus.

B-cell epitopes

During rubella infection, antibody responses are produced against all three structural proteins, but the E1 protein appears to be immunodominant (Table 2) (Cusi et al. 1989; Chaye et al. 1992a; Wolinsky et al. 1991). Studies using murine monoclonal antibodies have identified several epitopes on E1; three of these exhibit neutralizing or hemagglutinating activity, and have been mapped to residues 245–285 (Terry et al. 1988). A further well-conserved neutralization domain has been identified within residues 211–239 (Chaye et al. 1992b; Mitchell et al. 1992b; Wolinsky et al. 1993). Human sera react with synthetic peptides comprising residues 214–285 of the E1 protein, suggesting that this region may represent a major neutralization domain. A recombinant protein containing these epitopes is recognized by most rubella antibody-positive human sera (Starkey et al. 1995). Murine and human antibody-binding domains also occur outside this region (Ilonen et al. 1992; Mitchell et al. 1993; Newcombe et al. 1994). A neutralization epitope has also been identified on the E2 glycoprotein (1–26) (Dorsett et al. 1985); other epitopes have been located between amino acids 51 and 105. At least two epitopes are present on the C protein (residues 9–29 and 64–97) (reviewed by Frey 1994). However, the epitopes that confer protection are probably conformational (Wolinsky et al. 1991) and have not yet been identified.

T-cell epitopes

Rubella virus-specific cellular immune responses have been measured in vitro by lymphoproliferation assays and lymphocyte-mediated cytotoxicity assays. All three structural proteins contain T-cell epitopes. Immunoreactive regions have been identified within capsid protein residues 9–29, 119–152, 255–280, E2 residues 54–74 and E1 residues 213–239, 273–284, 358–377, and 389–422 (Ou et al. 1993; reviewed by Chantler et al. 2001). MHC-restricted cytotoxic T-cell responses have been described (reviewed by Chantler et al. 2001). The significance of these T-cell epitopes in relation to protection is unclear.

Biological, antigenic, and nucleic acid sequence variation

Differences in the biological activity of attenuated and wild-type strains have been reported. The attenuated Cendehill strain has lower infectivity for rabbits and other laboratory animals than wild-type strains (Zygraich et al. 1971; Gill and Furesz 1973). Ohtawara and colleagues (1985) demonstrated that the growth of Japanese vaccine strains is restricted at 39°C, the body temperature of the rabbit, suggesting that the attenuated strains are temperature-sensitive mutants. Chantler and colleagues (1993) have shown that the vaccine strains RA27/3 and Cendehill differ from wild-type strains in growth characteristics, plaque morphology, and temperature sensitivity. They have suggested that the processing in the Golgi of the viral glycoproteins from the attenuated strains was slower than for wild-type strains, particularly in synovial cells (a human chondrocyte cell line and synovial membrane cells). The growth of the HPV77-DE5 vaccine strain was similar to the M33 strain

from which it was derived. More recently, the slower replication of the Cendehill strain has been confirmed and both wildtype and attenuated strains have been shown to induce apoptosis (Domegan and Atkins 2002; Cooray et al. 2003).

Many studies in the late 1960s and 1970s failed to reveal any antigenic variation among RUBV strains and there was no reliable test to distinguish wild and attenuated strains. However, differences have been observed by cross-neutralization tests and neutralization kinetics (reviewed by Banatvala and Best 1990). More recent studies with monoclonal antibodies used in neutralization, HAI and enzyme immunoassay (EIA) revealed no significant differences between nine RUBV strains tested, which included the vaccine strains Cendehill, RA27/3, HPV77-DE5, and TO336 (Best et al. 1992). However, Dorsett et al. (1985) demonstrated strain-specific epitopes within the E2 glycopolypeptide when disrupted virus was used.

RUBV is genetically stable when compared to other RNA viruses. Although there is only one serotype of Rubella virus (Best et al. 1992), two genotypes have been identified (Bosma et al. 1996; Frey et al. 1998). Genotype 1 was isolated from cases in Europe, North America, and Japan between 1966 and 1996. Genotype 2 was isolated from cases in India and China in the 1990s and has more recently been detected in Italy (Zheng et al. 2003). A variable region (aa 697–800) has been identified within the gene coding for NSP1 (Hofmann et al. 2003). Nucleic acid sequencing has revealed that five characteristic nucleotide changes found within a 1 300 nucleotide sequence of the E1 coding region of the RA27/3 vaccine strain distinguishes it from other isolates of RUBV (Frey and Abernathy 1993; Frey 1994). Despite this, the deduced amino acid sequence of RUBV is remarkably stable (0.0–2.9 percent) although the amino acid sequence of E1 is more variable (Bosma et al. 1996; Frey et al. 1998; Hofmann et al. 2003).

CLINICAL AND PATHOLOGICAL ASPECTS

Introduction

In 1941, N. McAlister Gregg, an Australian ophthalmologist, published his now famous retrospective study 'Congenital cataract following german measles in the mother,' in which he showed that, if acquired in early pregnancy, rubella could cause congenital malformations

(Gregg 1941). Seventy-eight babies, all with a similar type of congenital cataract, were born in New South Wales after an extensive rubella epidemic there in 1940 and many of the mothers gave a history of rubella, usually in the first or second month of pregnancy. Congenital defects of the heart were also noted in 66 percent of cases whose cardiac condition was recorded. These findings were soon confirmed in Australia, and deafness was also noted in many congenitally infected infants. Microcephaly, dental defects, and low birth weight were also reported.

Despite confirmation of Gregg's original observation, an annotation in the *Lancet* (Editorial 1944) suggested that additional studies were required, as it could not be proved that the illness with rash experienced by these mothers was in fact rubella and that it was unlikely that such an association would have previously gone unnoticed. However, Hope-Simpson (1944) reported in the *Lancet* congenital cataract and heart defects in two babies in England after epidemic rubella. Similar defects had been noted before Gregg's original observation, but their significance had not been appreciated. Additional retrospective studies reporting congenital defects induced by rubella in early pregnancy were subsequently carried out (reviewed by Hanshaw et al. 1985).

Variable results were obtained in retrospective studies carried out before the isolation of rubella virus in 1962. When the starting point for investigations was an infant with one or more rubella-induced deformities results suggested that a very high proportion of mothers who had rubella during pregnancy were delivered of infants with congenital malformations. The outcome of pregnancies in which maternal rubella was followed by the birth of unaffected infants was not recorded. In 1940, when rubella was at its peak incidence in New South Wales, Gregg and colleagues (1945) reported that 96 percent of infants whose mothers had had rubella in early pregnancy suffered from congenital defects that were confined to cases in which maternal rubella had occurred before the 16th week of gestation.

In the period 1963–1964, within a year of the first reports of RUBV isolation and detection of rubella antibodies by neutralization tests, the USA experienced one of the most extensive outbreaks of rubella ever recorded. During this epidemic it was shown that maternal rubella could result in a generalized and persistent fetal infection and that infants excreted virus not only at birth but also for many months after this, despite developing rubella-specific antibody responses. In addition, the spectrum of anomalies was much wider than had hitherto been described. The impact of this epidemic stimulated research into the development of rubella vaccines and, following this, attenuated vaccines were licensed for use, in the USA in 1969 and in Britain in 1970. Congenitally acquired rubella, therefore, became a potentially preventable disease. National programs, which achieved high uptake rates, have recently shown a marked reduction in both postnatally and congenitally acquired rubella.

Postnatally acquired infection

CLINICAL AND VIROLOGICAL FEATURES

After an incubation period of 14–21 days, the characteristic features of rubella, rash, and lymphadenopathy may appear. In young children the onset of illness is usually abrupt. Such constitutional symptoms as fever and malaise may be present for a day or two before onset of the rash, but they usually subside rapidly after its appearance. Older children and adults may experience more pronounced constitutional symptoms 3–4 days before the rash appears, and during this prodromal phase an enanthem consisting of erythematous pinpoint lesions on the soft palate may be present. The exanthem is usually discrete, in the form of pinpoint maculopapular lesions. It appears first on the face and spreads rapidly to the rest of the body; lesions on the body may coalesce. The rash usually persists for about 3 days, occasionally longer, but may be fleeting. The mechanism by which rash is induced has not been established. Although immunopathological mechanisms may be responsible, RUBV has been isolated from skin biopsy specimens taken not only from areas with rash, but also from parts of the skin without rash and from the skin of patients with subclinical infection (Heggie 1978). Furthermore, the development of rash may be prevented by the administration of pooled human immunoglobulin, although this does not prevent viremia. Patients may complain of tender lymph nodes when or just before the rash appears. Follow-up studies of susceptible people exposed to rubella have revealed that lymphadenopathy may be present 7–10 days before the onset of rash, and sometimes for an even longer period after it has disappeared. Suboccipital, postauricular, and cervical lymph nodes are most frequently affected. Rubella is rarely associated with severe complications. Encephalitis may occur in one in 5 000–10 000 cases, but in general the prognosis is good (Krugman and Ward 1968). Very occasionally, there is clinical evidence of thrombocytopenia, which may result in purpuric rash, epistaxis, hematuria, and gastrointestinal bleeding.

The most common complication of postnatally acquired rubella is joint involvement. Although this is rare among children and adult males, it may occur in up to 60 percent of postpubertal females. Symptoms generally develop as the rash subsides and vary in severity from mild stiffness of the small joints of the hands to a frank arthritis with severe pain, joint swelling, and limitation of movement. The finger joints, wrists, knees, and ankles are most frequently affected. The duration of these symptoms is usually about 3 days, but occasionally they may persist for up to a month. Rubella-induced arthralgia is not associated with any sequelae. Arthralgia

also occurs in postpubertal females after administration of rubella vaccine. The mechanism by which naturally acquired and vaccine-induced infection causes arthralgia is probably complex. Thus, joint symptoms may result from direct infection of the synovial membrane by virus, as RUBV has been isolated from the joint aspirates of vaccinees with vaccine-induced arthritis (Weibel et al. 1969). Furthermore, studies in vitro have shown that attenuated virus strains will replicate in human synovial membrane cell cultures (Grayzel and Beck 1971). However, an immune mechanism is probably also involved, because, in addition to virus, joint aspirates have been shown to contain rubella-specific IgG (Ogra and Herd 1971; Mims et al. 1985), which suggests that joint symptoms may be induced by immune complexes. It is therefore of interest that the presence of rubella antibody containing immune complexes in the serum has been associated with a high incidence of joint symptoms following rubella vaccination (Coyle et al. 1982). However, hormonal factors may also play a role, for, in addition to being common in postpubertal females, the development of joint symptoms appears to be related to the menstrual cycle. After rubella vaccination, they are most likely to occur within 7 days of the onset of the cycle (Harcourt et al. 1979).

RUBV has been suggested as a possible cause of chronic inflammatory joint disease, but studies on patients with that disease have yielded conflicting and unconfirmed results. In the 1980s it was claimed that RUBV could be detected in synovial fluid or the synovium, as well as in lymphocytes from patients with both rheumatoid arthritis and seronegative arthritis (i.e. rheumatoid factor negative), but these reports have not been confirmed. However, it is known that RUBV is able to establish persistent infection in vivo (Waxham and Wolinsky 1984), as well as in human synovial cell cultures and organ cultures (Cunningham and Fraser 1985; Miki and Chantler 1992) and that high levels of rubella antibody are found in joint fluid (Mims et al. 1985). Although there is no doubt that RUBV may be isolated from synovial fluid after naturally acquired infection or vaccination and from occasional patients with chronic inflammatory joint disease (Report 1994; Bosma et al. 1998), recent studies show that rubella vaccination is not associated with chronic inflammatory joint disease.

DIFFERENTIAL DIAGNOSIS

Rubella is often difficult to diagnose clinically because the illness may present atypically with minimal lymphadenopathy and an evanescent rash, and, conversely, typical rubelliform rashes may be induced by other viruses (Ramsay et al. 2002). Thus, such viruses as enteroviruses, human herpesviruses 6 and 7, West Nile virus and dengue virus may occasionally induce rubella-like rashes. Chikungunya virus and Ross River virus (Togaviruses) and parvovirus B 19 (Parvoviruses) may induce not only a rubella-like rash, but also arthralgia. Serological studies have shown that there is poor correlation between a past history of rubella and immune status, particularly among adults (Brown et al. 1969). This is not surprising because not only may rubella present atypically, but disease without rash or subclinical infection may occur in up to 25 percent of children (Krugman and Ward 1954; Green et al. 1965).

The relation between clinical and virological features is shown in Figure 3. The patient is potentially infectious for a prolonged period, as pharyngeal virus excretion may occur for up to a week before onset of rash and persist thereafter for 7–10 days. Virus may also be detected in the stools and urine, but excretion occurs for a shorter time. These are not suitable specimens from which to isolate virus and do not play an important role in virus transmission. Viremia is present for about a week before the onset of rash, but as this appears rubella antibodies develop and viremia terminates.

EPIDEMIOLOGY

Rubella has a worldwide distribution. In temperate climates, before the introduction of rubella vaccination, epidemics usually occurred in spring and early summer, rubella occurring less commonly among preschool children than among schoolchildren and young adults. Women of child-bearing age were often infected as a result of exposure to their own children or at work. Seroepidemiological studies showed that the proportion of seropositive people increased progressively with age, about 50 percent of 9- to 11-year-old children being immune. Among women of child-bearing age, the proportion increased to about 80–85 percent (Dowdle et al. 1970). In industrialized parts of the world (e.g. UK, USA, Sweden, and Finland), which have achieved high uptake rates for rubella vaccine, postnatally and congenitally acquired rubella are now rare. However, in the UK, there is still a pool of rubella-susceptible males who have not been vaccinated. Many young men were infected in localized outbreaks of rubella in 1993 and 1996 (Figure 4), transmitting infection to some susceptible pregnant women, most of them being young primigravidae and many of whom were immigrants (Miller et al. 1997, www.hpa.org.uk/infections). Immigrants from Asia are at particular risk, as up to 23 percent may be susceptible (Tookey et al. 2002). Despite the success of the rubella vaccination program in the USA, a number of cases of congenitally acquired rubella were reported in California among immigrant women and among the Amish population in Pennsylvania in 1989/1990, this resulting from infection of unvaccinated women (Lindegren et al. 1991).

During the last few years, several studies have demonstrated that there is a considerable problem of

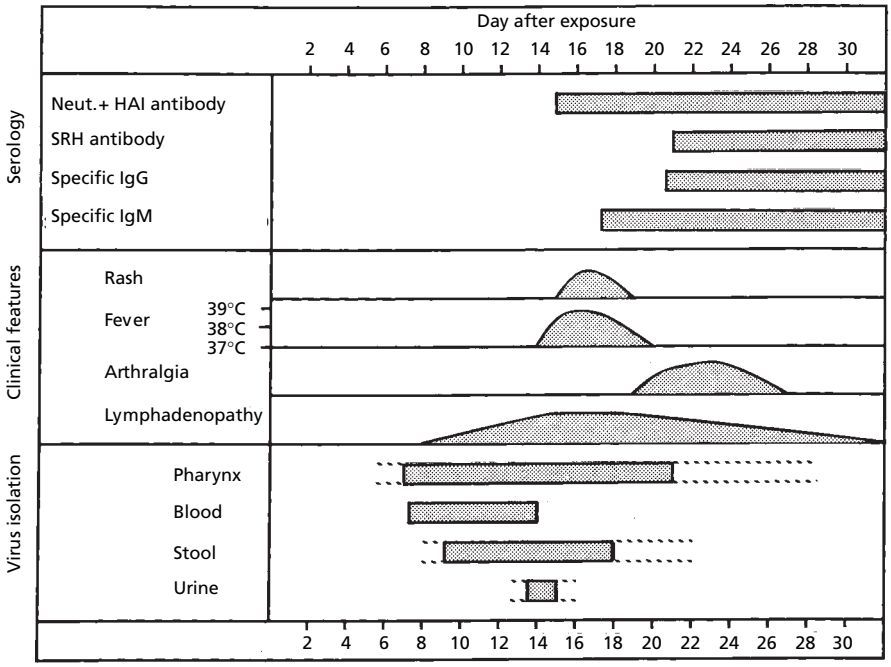

Figure 3 *Relationship between clinical and virological features of postnatally acquired rubella. HAI, hemagglutination inhibition; Neut., neutralizing; SRH, single radial hemolysis.*

congenital rubella in developing countries (Cutts et al. 1997; WHO 2000a, c). Such countries have an annual incidence of 0.6–4.1 cases per 1 000 live births, usually associated with rubella outbreaks. This is similar to the incidence in developed countries before the introduction of rubella vaccination. Epidemics of rubella occur every 4–7 years. The proportion of women susceptible to rubella has been shown to be 15–20 percent in many areas, although there may be considerable variation between different areas of a country, with susceptibility usually being higher in rural than in urban areas (Cutts et al. 1997). In some countries ⩾25 percent are susceptible. Particularly high susceptibility rates occurred in island populations, including Jamaica and Trinidad and Tobago. An increasing number of countries are addressing this problem by including rubella vaccination in their national immunization programs (see Vaccination programs).

IMMUNE RESPONSES

Rubella-specific IgG, IgM, and IgA responses develop rapidly after the onset of rash. Rubella-specific IgG persists for life, but may decline to low levels in old age. The IgG response is predominantly IgG1. IgG3 is detected in most sera from cases of recently acquired rubella and IgG4 occasionally in sera from cases of remote rubella (Stokes et al. 1986; Thomas and Morgan-Capner 1988). Rubella-specific IgM usually appears within 4 days of onset of rash and persists for 4–12 weeks, but detection depends on the sensitivity of the technique employed. Specific IgM may sometimes persist for up to 1 year after both naturally acquired infection and rubella immunization (Pattison et al. 1975; O'Shea et al. 1985). Serum and nasopharyngeal IgA responses are detectable for at least 5 years after infection. The specific serum IgA response is exclusively IgA1. Specific IgD and IgE responses develop rapidly after onset of infection and persist for at least 6 months. The results of Mitchell and colleagues (1992a) suggest that males have a more rapid antibody response than females. Methods available for the detection and quantification of rubella antibodies are discussed under Laboratory diagnosis.

Immunoblotting for detection of polypeptide-specific antibodies is technically difficult. However, Zhang et al. (1992) demonstrated that antibodies to E1 and E2 were detected more effectively under nonreducing conditions than in the presence of 2-mercaptoethanol. The response to E1 is greater than to E2 and there is a strong response to the capsid protein (C) (Zhang et al. 1992; Nedeljkovic et al. 1999). Antibodies to E1 are essential for protection (Cusi et al. 1995). Avidity of IgG antibody to E1 matures during the 2 years after rubella infection, but IgG anti-E2 and anti-C show minimal avidity maturation (Mauracher et al. 1992).

A decrease in total leukocytes, neutrophils, and T cells, and a transient depression of lymphocyte responsiveness to mitogens and antigens such as purified protein derivative (PPD) is seen after rubella (Buimovici-Klein et al. 1976; Maller et al. 1978; Niwa and Kanoh 1979; Hyypiä et al. 1984). Cell-mediated immune responses, measured by lymphocyte proliferation assays, develop within a few days of onset of rash and persist for many years. Lymphokine secretion has also been detected (Honeyman et al. 1974; Buimovici-Klein and Cooper 1985). MHC class I-restricted $CD8^+$ cytotoxic T lymphocytes have been demonstrated in rubella-immune individuals (Lovett et al. 1993).

RE-INFECTION

Natural infection is followed by protection from reinfection, except in rare cases. However, evidence of reinfection may occasionally be obtained by demonstrating a significant increase in antibody concentration following natural and experimental exposure to rubella. Such reinfection is generally asymptomatic (Horstmann et al. 1970; Vesikari 1972). Reinfection in pregnancy is hazardous only if viremia occurs, and this has rarely been documented in experimental studies (O'Shea et al. 1983). Following maternal reinfection during the first 16 weeks in pregnancy, the risk of fetal infection has been estimated to be no more than 8 percent, and fetal damage is rare (Best et al. 1989; Morgan-Capner et al. 1991). Although it is possible that, in such cases, transmission of virus to the fetus may be due to a specific defect in the maternal immune response, rubella reinfection is not associated with a lack of neutralizing antibodies or persistent impairment of rubella-specific lymphoproliferative responses (O'Shea et al. 1994). Sequence changes have not been identified in the E1 ORF of isolates from cases of reinfection (Bosma et al. 1996). Further studies are required to determine whether reinfection is due to a failure to produce an immune response to the protective epitopes of the virus. Reinfection in pregnancy will be eliminated if high rates of rubella vaccination are achieved and maintained among the target groups (see Vaccination programs). Rubella reinfection has been reviewed by Best (1993) and Bullens et al. (2000).

Congenitally acquired infection

CLINICAL MANIFESTATIONS

Although the early retrospective enquiries emphasized the frequency and importance of such defects as congenital anomalies of the heart and eyes, and deafness, it was not until follow-up studies had been carried out on infants whose mothers had had rubella during the extensive 1963–1964 outbreak in the USA that it was fully appreciated that congenital rubella frequently caused widespread multisystem disease. Follow-up studies showed that congenital rubella syndrome (CRS) was not a static disease and that prolonged careful evaluation of infants at risk was necessary before some or all of the features of CRS were apparent. The broader range of anomalies described after the US 1963/1964 and subsequent outbreaks were probably not due to any change in viral virulence, but rather to more careful and prolonged observation. Careful scrutiny of the records of infants with CRS who were born before these outbreaks revealed that such anomalies as thrombocytopenic purpura and osteitis, although not reported in the literature, occurred fairly frequently.

Cooper (1975) divided clinical features associated with rubella infection into those that were transient, developmental, or permanent (Table 3). The pathogenesis of transient lesions is not understood, but they are usually present only during the first few weeks of life, do not recur and are not associated with the development of permanent sequelae. Intrauterine growth retardation resulting in low birth weight but at a normal gestational

Table 3 *Clinical features associated with congenitally acquired rubella (adapted from Cooper 1975)*

	Common	Uncommon
Transient	Low birth weight	Cloudy cornea
	Thrombocytopenic purpura	Hepatitis
	Hepatosplenomegaly	Generalized lymphadenopathy
	Bone lesions	Hemolytic anemia
	Meningoencephalitis	Pneumonitis
Developmental	Sensorineural deafness	Severe myopia
	Peripheral pulmonary stenosis	Thyroiditis
	Mental retardation	Hypothyroidism
	Central language defects	Growth hormone deficiency
	Diabetes mellitus	'Late onset disease'
Permanent	Sensorineural deafness	Severe myopia
	Peripheral pulmonary stenosis	Thyroid disorders
	Pulmonary valvular stenosis	Dermatoglyptic abnormalities
	Patent ductus arteriosus	Glaucoma
	Ventricular septal defect	Myocardial abnormalities

	Psychomotor retardation	
	Microcephaly	
	Cryptorchidism	
	Inguinal hernia	
	Diabetes mellitus	

age ('small for dates' babies) is among the most common of the transient features. Thus, Cooper and colleagues (1965) found that about 60 percent of infected infants fell below the tenth, and 90 percent below the 50th percentile.

A petechial or purpuric rash is also common, particularly among infants whose mothers had had maternal rubella in early pregnancy (Figure 5) (Cooper et al. 1965; Horstmann et al. 1965). However, low birth weight and a purpuric rash are seldom the sole manifestations of congenital rubella. These infants may have other anomalies, such as congenital heart and eye defects, although they may not always be apparent at birth. Infants with thrombocytopenic purpura generally have a platelet count ranging from 3 000 to 100 000/mm^3, this being associated with a decreased number of megakaryocytes, but of normal morphology, in the bone marrow. In general, the platelet count rises spontaneously during the first month of life, although (rarely) some infants die from such complications as intracranial hemorrhage.

OCULAR DEFECTS

Many of the ocular defects characteristic of CRS were described by Gregg (1941), who drew particular attention to pigmented retinopathy and cataract. Pigmented retinopathy may be present in up to 50 percent of infants with CRS (Menser and Reye 1974; Vijayalakshmi et al. 2002) and may provide a useful aid in clinical diagnosis. The macular area of the retina is generally affected, but the lesions rarely impair vision. Cataracts may be unilateral or bilateral. Although usually present at birth, they may not be visible until several weeks later (Murphy et al. 1967). Lesions may be subtotal, consisting of a dense pearly-white central opacity (Figure 6) or, total with a more uniform density throughout the lens. Microphthalmus and iris hypoplasia are often associated with congenital cataract, but glaucoma is less common. However, it is important to recognize glaucoma as it can rapidly lead to blindness. Strabismus and nystagmus are also common (Vijayalakshmi et al. 2002).

Microphthalmia and glaucoma result from disturbances in organogenesis, and retinopathy and cataract result from intrauterine tissue destruction. However, delayed manifestations of congenital infection have also been recorded including lens changes, chronic uveitis, glaucoma, choroidal neovascularization, corneal hydrops, and keratoconus. Mechanisms postulated include virus persistence in the eye, resulting in RUBV-induced reduced growth rate and lifespan of cells, autoimmune phenomena or virally induced vascular damage and reactive hypervascularization (reviewed by Arnold et al. 1994).

DEAFNESS

Of the permanent defects, the most common is sensorineural deafness. This results from rubella-induced

Figure 5 *Purpuric rash in newborn infant with congenitally acquired rubella, who was subsequently found to have congenital heart disease and cataract.*

damage to the organ of Corti. However, central auditory impairment may also occur. Hearing loss, which may be unilateral or bilateral, mild or profound, may sometimes be the only rubella-induced congenital anomaly.

Peckham (1972) followed up 218 children who were apparently normal at birth, but who had been exposed to rubella in utero. When assessed for hearing loss at the age of 1–4 years, 50 (23 percent) were deaf. When 85 were re-examined between the ages of 6 and 8 years, further hearing defects were detected in another nine children. Of the children with hearing defects, 90 percent were seropositive. Because rubella antibodies are uncommon before the age of 4 years, it is particularly important to follow up infants with persistent rubella antibody so that hearing defects can be recognized as early as possible. Hearing defects can be detected in early infancy by testing auditory brainstem responses and otoacoustic emissions (Van Straaten et al. 1996).

Figure 6 *Congenital rubella cataract in a 9-month-old infant. Cataract present in the left eye was surgically removed.*

HEART DISEASE

Congenital anomalies of the cardiovascular system are responsible for much of the high perinatal mortality associated with CRS. Numerous studies have shown that the most common lesions are persistence of a patent ductus arteriosus, proximal (valvular) or peripheral pulmonary artery stenosis, and a ventricular septal defect (Sperling and Verska 1966; Hastreiter et al. 1967; Cooper 1975).

Occasionally, neonatal myocarditis is found, often associated with other cardiac malformations (Korones et al. 1965). Rubella-induced damage to the intima of the arteries may result in obstructive lesions in the renal and pulmonary arteries (Rorke and Spiro 1967; Phelan and Campbell 1969).

DEFECTS IN THE CENTRAL NERVOUS SYSTEM

About 25 percent of infants who present at birth with clinical evidence of CRS have central nervous system (CNS) involvement, usually in the form of a meningoencephalitis. Such infants are often lethargic at birth, but may become irritable and often exhibit evidence of photophobia. They have a full anterior fontanelle, pleocytosis, and an increased amount of protein in the cerebrospinal fluid (CSF) (Desmond et al. 1967). The outcome is variable and unpredictable. Although approximately 25 percent of infants presenting with meningoencephalitis at birth may, by the age of 18 months, be severely retarded, suffering from communication problems, ataxia, or spastic paresis, others appear to progress well neurologically despite poor development in the first 6 months of life.

Rubella panencephalitis is rare. Only about 50 cases have been reported, the majority as a consequence of congenital rubella infection, although it has also been reported following postnatally acquired disease. Most patients with CRS develop clinical signs between the ages of 8 and 20 years (reviewed by Frey 1997). RUBV has been recovered from the brain both with and without cocultivation techniques. It has also been recovered from patients' lymphocytes (Cremer et al. 1975; Wolinsky et al. 1979). Elevated levels of rubella-specific IgG and occasionally IgM may be detected in the serum.

The CSF may contain elevated concentrations of protein and immunoglobulin. Oligoclonal bands and a high CSF: serum rubella antibody ratio may be present suggesting intrathecal production of antibodies (Wolinsky et al. 1982).

Histological studies show panencephalitis with a perivascular inflammatory response, as well as a vasculitis. Rubella antigens have not been detected in brain sections by immunofluorescence. It has been postulated that post-rubella panencephalitis may be mediated by immune complexes (Waxham and Wolinsky 1984) or by virus-mediated autoreactivity to brain antigens (Martin et al. 1989).

DIABETES

Diabetes mellitus was originally believed to be a rare complication of CRS. However, follow-up studies of infants infected in utero during the Australian and US epidemics of 1940 and 1963/1964, respectively, have shown that nine of 45 (20 percent) of Australian and 30 of 242 (12.4 percent) of US children eventually developed insulin-dependent diabetes mellitus (IDDM). Up to 40 percent of CRS patients have impaired glucose tolerance (See and Tilles 1998). A long latent period is characteristic, the mean age of children developing IDDM in the US study being 9 years; all the Australian patients were in their third decade (Menser et al. 1978; Ginsberg-Fellner et al. 1985). Lymphocytic infiltration of the pancreas of an infant with CRS, but without IDDM may suggest that RUBV can initiate a train of events that subsequently results in IDDM in later life (Bunnell and Monif 1972). It seems likely that autoimmune mechanisms are involved in the pathogenesis of IDDM, because the HLA types in these patients are typical of those with autoimmune disease, there being a significant increase in prevalence of HLA-DR3, some increase in HLA-DR4 and a virtual absence of HLA-DR2. In addition, islet cell antibodies have been detected in 20 percent of these patients. These antibodies have a cytotoxic effect on cultured islet cells and predict the diabetic state. Although autoimmune responses may play an important role, the mechanism by which RUBV might trigger them remains to be established. An experimental study employing human fetal islet cells showed that RUBV induced a depression of immunoreactive secreted insulin without being cytolytic (Numazaki et al. 1990). A further study suggested that autoimmune phenomena might be involved, because immunoreactive epitopes in the RUBV capsid shared antigenicity with islet β cell protein (molecular mimicry) (Karounos et al. 1993).

BONE DEFECTS

Bone lesions may be detected by X-ray. Irregular areas of translucency are present in the metaphyseal portion of the long bones, but there is no evidence of periosteal reaction in over 20 percent of infants with congenital rubella (Cooper et al. 1965). These lesions generally resolve within 1–2 months. Cooper et al. (1965) detected these characteristic radiological changes in a fetus of 18 weeks' gestational age, suggesting that the process inducing such changes begins in early gestational life.

LATE ONSET DISEASE

Between the ages of about 3 and 12 months, some infants may present with such features as a chronic rubelliform rash, persistent diarrhea and pneumonitis. Marshall (1973) referred to this syndrome as 'late onset disease.' Although mortality is high, some infants show a dramatic response to treatment with corticosteroids. This syndrome may reflect an immunopathological phenomenon. Circulating immune complexes that appear to contain rubella antigen have been demonstrated in infants with late onset disease (Tardieu et al. 1980), and Coyle and colleagues (1982) demonstrated rubella antibody containing immune complexes in children with congenital rubella who developed new clinical problems some years after birth.

Some developmental defects may take many months or years to become apparent, but then persist permanently. Failure to recognize such defects in early infancy may not always be the result of difficulty in their detection. There is evidence which suggests that such defects as perceptive deafness, CNS anomalies and some ocular defects may actually develop or become increasingly severe some considerable time after birth. Menser and Forrest (1974) showed that it might be up to 4 years before the first rubella defects were recognized. Further defects might continue to be recognized up to the age of 8 years. The progressive nature of congenitally acquired disease is emphasized by the finding that children with previously stable congenital rubella-induced defects developed a widespread subacute progressive panencephalitis with progressive motor retardation as late as the second decade in life (Townsend et al. 1975; Weil et al. 1975).

LONG-TERM FOLLOW-UP OF CRS

As a result of the extent and severity of rubella-induced congenital malformations, children who survive will need continuous specialized management, education, and rehabilitation. However, a study carried out on 50 25-year-old patients with CRS born in Australia after the 1940/1941 epidemic showed that, although many were deaf or had eye defects, they had developed far better than had been anticipated when assessed in early childhood. Many had married and produced normal children, and all but four were employed, most patients being of average intelligence (Menser et al. 1967a). Follow-up studies so far reported on children with CRS following the 1963/1964 US rubella epidemic suggest that it may have had a more catastrophic impact on the lives of affected children than did the 1940/1941

Australian epidemic (Cooper 1975). This may be a reflection on the more modern methods of treatment available to the children born after this more recent epidemic. Many might not have survived previously.

Although congenitally acquired rubella is now rare in countries that have adopted rubella vaccination programs, a heavy burden from previous epidemics persists. A 20-year follow-up on 125 patients infected during the extensive 1963–1965 USA outbreak showed that, although many patients had multiple defects, ocular disease was the most commonly noticed disorder (78 percent) followed by sensorineural deafness (66 percent), psychomotor retardation (62 percent), and cardiac anomalies (58 percent). A 60-year follow-up of the Australian cohort has shown that the prevalence of diabetes, thyroid disorders, early menopause, and osteoporosis is higher in those with CRS than in the general population (Forrest et al. 2002).

Pathogenesis

The fetus is at risk during the period of maternal viremia, because placental infection may occur at this time. The most likely source of virus is from the maternal viremia. Virus may also be excreted via the cervix for up to 6 days after the onset of rash (Seppala and Vaheri 1974), and, because virus may exist in the genital tract for even longer, placental infection by direct contact or from ascending genital infection cannot be excluded.

After infection in early pregnancy, rubella induces a generalized and persistent virus infection in the fetus, which may result in multisystem disease. Töndury and Smith (1966) conducted histopathological studies on the products of conception from mothers clinically diagnosed as infected with rubella: anomalies were present in 68 percent of 57 fetuses when maternal rubella was contracted in the first trimester. When contracted in the first month of pregnancy, 80 percent were abnormal, sporadic foci, or cellular damage being present in the heart, inner ear, lens, skeletal muscle, and teeth. It was suggested that RUBV enters the fetus via the chorion, in which it induces necrotic changes in the epithelial cells, as well as in the endothelial lining of the blood vessels. The damaged endothelial cells are desquamated into the lumen of the vessel and then transported as virus-infected 'emboli' into the fetal circulation to settle in and infect various fetal organs. Lesions in the chorion were present as early as the tenth day after the onset of maternal rash. Fetal endothelial damage was distributed widely and probably resulted from viral replication rather than from antibody-mediated damage, because the most extensive histopathological changes were present at a gestational period before the fetal immune defense mechanism was sufficiently mature to be activated. Indeed, a characteristic feature of rubella embryopathy following maternal rubella in early gestational life is the notable absence of an inflammatory cell response (Töndury and Smith 1966).

At least three mechanisms have been suggested for inducing fetal damage: a virus-induced retardation in cell division, apoptosis (Pugachev and Frey 1998b), and tissue necrosis. Studies in vitro on embryonic cell cultures and rubella-infected fetuses suggest that RUBV may induce chromosomal damage and cause cells to divide more slowly than those that are uninfected (Plotkin et al. 1965). This may be due to a specific protein that reduces the mitotic rate of infected cells (Plotkin and Vaheri 1967). If retardation of cell division occurs during the critical phase of organogenesis, it is likely to result in congenital malformations. It has also been shown that the organs of rubella-infected infants are smaller and contain fewer cells than those of uninfected infants (Naeye and Blanc 1965). The fetal endothelial damage induced by rubella infection may cause hemorrhages in small blood vessels, leading to tissue necrosis and further damage of malformed organs over a longer period. Such organs as the liver, myocardium, and organ of Corti may be affected. Studies on the products of conception obtained from virologically confirmed cases of rubella during the first trimester have shown that the fetus is almost invariably infected, regardless of the time at which infection has occurred during this period (Rawls 1968; Thompson and Tobin 1970). It has also been suggested that RUBV may interfere with organ growth by preventing the assembly of actin and interrupt the cell cycle by binding to the tumor suppressor protein pRB (reviewed by Lee and Bowden 2000).

RUBV is isolated infrequently from neonates whose mothers developed infection after the first trimester, possibly because by then fetal immune mechanisms can effectively terminate infection. More mature fetal tissues do not have a reduced susceptibility to infection, for studies in vitro have shown that RUBV will replicate as well in organs derived from fetuses of 12–13 weeks' gestational age as in those of younger fetuses (Best et al. 1968). Nevertheless, even though severe congenital anomalies are rarely encountered following rubella after the first trimester, serological evidence of fetal infection has been shown to occur in 25–33 percent of infants whose mothers acquired maternal rubella between the 16th and 28th weeks of gestation (Cradock-Watson et al. 1980; Vejtorp and Mansa 1980).

Persistence of virus

Following intrauterine infection in early pregnancy, RUBV persists throughout gestation and can be isolated from most organs obtained at autopsy from infants who die in early infancy with severe and generalized infections. Virus may also be recovered from the nasophar-

yngeal secretions, urine, stools, CSF, and tears of survivors. RUBV can be isolated from nasopharyngeal secretions of most neonates with severe congenitally acquired disease, but by the age of 3 months the proportion excreting virus has declined to 50–60 percent and by 9–12 months to 10 percent (Cooper and Krugman 1967). Particularly during the first few weeks after birth, those with severe disease may excrete high concentrations of virus and readily transmit infection to rubella-susceptible contacts. RUBV may persist in infants with CRS in secluded sites for even longer. Thus, RUBV has been recovered from a cataract removed from a 3-year-old child (Menser et al. 1967b) and from the CSF of children with CNS involvement up to the age of 18 months (Desmond et al. 1967). Rubella antigen was detected in the thyroid from a 5-year-old child with Hashimoto's disease by immunofluorescence (Ziring et al. 1977), and by cocultivation techniques RUBV was recovered from the brain of a child who developed rubella panencephalitis at the age of 12 years (Cremer et al. 1975; Weil et al. 1975). Experimental studies have shown that, within the CNS, the astrocyte is the main cell type in which RUBV replicates with high concentrations of virus being expressed. Intrauterine infection involving these cells may perhaps induce focal areas of necrosis resulting in the pattern of neurological deficit observed in CRS (Chantler et al. 1995).

How RUBV persists throughout gestation and for a limited period during the first year of life has not been clearly established. Possible mechanisms include defects in cell-mediated immunity (CMI), poor interferon synthesis, and the possibility that a limited number of infected fetal cells give rise to infected clones which persist for a limited period. It has also been suggested that selective immune tolerance to the RUBV E1 protein may play a role (Mauracher et al. 1993). Studies in vitro show that RUBV replicates in T lymphocytes and macrophages and can also persist in B lymphocytes, causing inhibition of host-cell protein synthesis (Chantler and Tingle 1980; van der Logt et al. 1980). Infection of macrophages may interfere with their interactions with T cells. Postnatally acquired rubella causes a transient reduction in lymphocyte responses to phytohemagglutinin (Buimovici-Klein et al. 1976; Maller et al. 1978; Vesikari 1980), as well as a decrease in the numbers of T cells (Niwa and Kanoh 1979). CRS might be expected to cause an even greater reduction in responsiveness. Indeed, significantly diminished lymphoproliferative responses to phytohemagglutinin and rubella antigen, as well as diminished interferon synthesis, were demonstrated in 40 congenitally infected children aged 1–12 years (Buimovici-Klein et al. 1979). Impairment of CMI responses was related to the gestational age at which maternal infection occurred, and was greatest in infants whose mothers acquired rubella in the first 8 weeks of pregnancy. Hosking and colleagues (1983) suggested that children with nerve deafness due to CRS could be distinguished from those with immunity due to postnatally acquired rubella by their failure to produce lymphoproliferative responses to rubella antigen. O'Shea and colleagues (1992) also found that 10 of 13 (80 percent) children with CRS under the age of 3 years failed to mount a lymphoproliferative response. Congenitally infected infants also have impaired natural killer cell activity (Fuccillo et al. 1974) and persistent T-cell abnormalities (Rabinowe et al. 1986). Defective CMI responses may persist into the second decade of life, well beyond the time when RUBV can be recovered from accessible sites.

Risks to the fetus

Whether maternal rubella induces fetal damage that causes intrauterine death or the birth of a malformed infant depends on the gestational age at which maternal rubella occurs, although other factors may also be involved. Maternal rubella may result in spontaneous abortion in up to 20 percent of cases (Siegel et al. 1971). This occurs most commonly when maternal infection is acquired during the first 8 weeks of pregnancy. To this must be added fetal wastage from therapeutic abortion following virologically confirmed rubella.

MATERNAL RUBELLA IN THE FIRST TRIMESTER

Many early prospective studies, the results of which are still quoted, underestimated the risks of congenital malformations, because maternal infections were included that were not rubella-induced and some rubella-infected infants were not followed up for sufficiently long. It is now known that 75–100 percent of infants born to mothers infected at this time will be congenitally infected and most of those infected will have associated defects (Enders 1982; Miller et al. 1982; Grillner et al. 1983). Many infants, although apparently normal at birth, if followed up for periods ranging from a few months to some years, may eventually be shown to have such defects as perceptive deafness or minimal CNS anomalies. Figure 7 relates the gestational age of maternal rubella to the clinical manifestations of congenitally acquired disease among 376 infants infected in utero during the 1964 epidemic in the USA. When maternal infection is acquired during the first 8 weeks of pregnancy – the critical phase of organogenesis – cardiac and eye defects are likely to occur. Retinopathy, hearing, and CNS defects are more evenly distributed throughout the first 16–20 weeks of gestational life.

MATERNAL RUBELLA AFTER THE FIRST TRIMESTER

RUBV is seldom isolated from infants whose mothers acquired rubella after the first trimester, although studies in vitro have shown that fetal tissues, regardless of gestational age, are susceptible to infection (Best

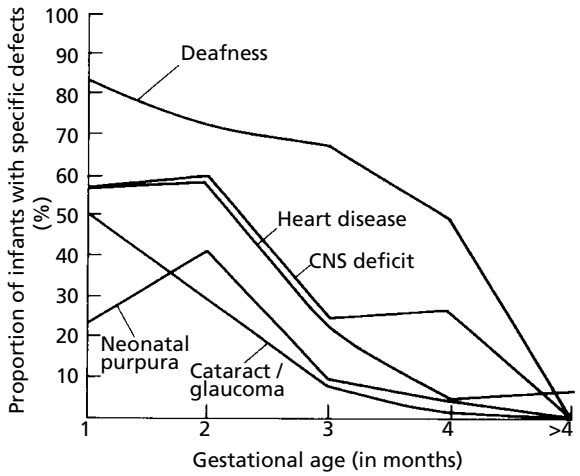

Figure 7 *Relation of clinical manifestations of congenital rubella to time of maternal infection, extrapolated from Cooper et al. (1969).*

et al. 1968). Indeed, serological studies confirm that a high proportion of infants are infected as a result of maternal rubella contracted after the first trimester, rubella-specific IgM being detected in 25–33 percent of infants whose mothers had rubella between the 16th and 20th weeks of pregnancy (Cradock-Watson et al. 1980). However, because organogenesis is complete by 12 weeks and in more mature fetuses immune responses may limit or terminate infection, such infants rarely have severe or multiple anomalies. Deafness and retinopathy, which per se does not affect vision, are likely to be the only anomalies commonly associated with rubella after the first trimester. When the results of four studies conducted in different countries are combined it is seen that the risk is about 17 percent when infection occurs at 13–16 weeks and about 5.9 percent after infection at 17–20 weeks (Peckham 1972; Miller et al. 1982; Grillner et al. 1983; Munro et al. 1987). Figure 7 shows that deafness is usually the sole clinical manifestation of fetal infection occurring between 13 and 16 weeks, and is relatively common, but that deafness or any other defects are only rarely encountered after this time.

PRECONCEPTUAL RUBELLA

Studies conducted in Germany and Britain indicate that preconceptual rubella does not result in transmission of RUBV to the fetus. Thus, Enders and colleagues (1988) found no serological or clinical evidence of intrauterine infection in 38 infants whose mothers' rashes appeared before or within 11 days after their last menstrual period (LMP). However, the fetus of a mother whose rash appeared 12 days after her LMP became infected, and all of ten mothers who developed rash 3–6 weeks after their LMP transmitted infection to their fetuses.

LABORATORY DIAGNOSIS

Rubella antibody screening

Tests for rubella antibodies are extensively used to identify susceptible women who should be offered rubella vaccination. In the UK, all antenatal patients are tested, as should women presenting to their general practitioners and 'well woman' clinics who have no history of vaccination or a previous positive antibody result (Department of Health 2003). A number of tests are available commercially. Enzyme-linked immunosorbent assay (EIA) is used widely because it is readily automated and can easily be included in automated antenatal screening. Latex agglutination (LA) has the advantage that a result is available in a few minutes. Single radial hemolysis (SRH) plates may be prepared in the laboratory with commercially available reagents. HAI is not recommended for screening since false-positive results may occur as a result of incomplete removal of β lipoprotein inhibitors of HA, and because it is more time consuming and labor intensive. These techniques have been described in detail by Best and O'Shea (1995). Vaccination should be offered to women who are seronegative or have antibody concentrations <10 IU/ml.

Rubella antibodies may be detected in oral fluid by IgG-capture radioimmunoassay (RIA) (GACRIA) (Parry et al. 1987). The use of oral fluid rather than serum has several benefits for seroepidemiological studies, especially those involving children and in developing countries, since it can be obtained by a noninvasive technique (Eckstein et al. 1996; Nokes et al. 1998).

Most rubella antibody tests use whole virus as antigen, but peptides and proteins produced by recombinant techniques have been evaluated (Mitchell et al. 1992b; Hobman et al. 1994c; Starkey et al. 1995) and some methods seem promising. One commercial test employed virus-like particles produced by expression in BHK cells (Grangeot-Keros et al. 1995).

Virus isolation and identification by RT-PCR

RUBV may be detected in clinical samples by isolation in cell culture or by reverse transcription polymerase chain reaction (RT-PCR). Preferred samples are a throat swab or oral fluid. Virus isolation techniques are rarely used for the diagnosis of postnatally acquired rubella because this may be established more reliably and rapidly by serological methods. However, virus isolation may be of value for determining the duration of excretion in congenitally infected infants, as they may transmit infection to susceptible contacts. RUBV isolates are also required to study the molecular epidemiology of the virus.

RUBV can be identified by the production of CPE in RK13, SIRC, and certain sublines of Vero cells, by interference in primary vervet monkey kidney (VMK) (Parkman et al. 1962) and other monkey kidney cultures, or by using immunofluorescence or immunoperoxidase for detection of antigen in such cells as RK13, BHK-21, and Vero. The most sensitive technique for isolation of RUBV is one or two passages in Vero cells, followed by passage in RK13 cells, in which the virus may be identified by immunofluorescence employing hyperimmune sera or monoclonal antibodies or by RT-PCR. These techniques have been described in detail by Best and O'Shea (1995). However, as virus isolation is labor intensive and a minimum of 3 weeks is required to obtain a result, this technique is available only in a few specialized laboratories.

Nested RT-PCRs for the detection of RUBV RNA employing primers from the E1 region have been described by Bosma et al. (1995b); Revello et al. (1997); Vyse and Jin (2002) and Li Jin (personal communication, 2003). Results of these assays compared well with virus isolation. RT-PCR is now used for the pre- and postnatal diagnosis of congenital rubella and is useful for detection of RUBV RNA in oral fluid when serological results are equivocal (Vyse and Jin 2002).

Laboratory diagnosis of postnatally acquired infection

A clinical diagnosis of rubella is unreliable and therefore laboratory confirmation is required, particularly for the diagnosis of rubella-like illness during pregnancy and for contacts of pregnant women. The detection of rubella-specific IgM is the method of choice. Specific IgM antibodies may be detected by indirect and M-antibody capture enzyme immunoassays. Care should be taken to ensure that the test chosen has a high degree of specificity and sensitivity (Hudson and Morgan-Capner 1996; Tipples et al. 2004). Rubella-specific IgM usually appears within 4 days of onset of rash and persists for 4–12 weeks. More than 4 weeks after onset, detection will depend on the sensitivity of the technique employed. The diagnosis should be confirmed by detecting a significant rise in antibody concentration or by testing a further serum for specific IgM. A significant rise in antibody concentration may be detected by a variety of methods, including HAI, EIA, or LA titration. Seroconversion can also be detected by SRH. Although HAI antibodies develop within a day or 2 of onset of rash, antibodies detected by EIA, LA, or SRH may be delayed until 7–8 days (Figure 3).

Rubella-specific IgG and IgM antibodies may be detected in oral fluid using antibody capture radioimmunoassays. Results correlate well with serum antibodies (Perry et al. 1993; Vyse et al. 1999). The optimum time for detecting specific IgM is 1–5 weeks after onset of illness. This method is particularly useful when testing children and has been used to demonstrate that many rubella-like rashes are caused by other viruses or bacteria (Ramsay et al., 1998, 2002).

RE-INFECTION

Reinfection is associated with a rise in antibody concentration, sometimes to very high levels. An IgM response may also be present, but is usually lower and more transient than that following primary infection. An accurate history of rubella contact, rubella vaccination, and previous rubella antibody screening is required in order to interpret results. It may be particularly difficult to distinguish between a primary infection and reinfection, if blood is not obtained shortly after contact or if sera taken prior to contact (e.g. for screening purposes) are not available. However, reinfection may be distinguished from primary infection by examining the antigen-binding avidity of specific IgG, because the avidity of specific IgG from cases of recent primary rubella is low compared with that from people with remote infection or reinfection (Thomas and Morgan-Capner 1991).

Testing for reinfection is not indicated in populations where most women are rubella seropositive and there is a low incidence of rubella (Morgan-Capner and Crowcroft 2002).

ASSESSMENT OF THE RISK TO WOMEN EXPOSED TO OR WHO DEVELOP RUBELLA-LIKE ILLNESS IN PREGNANCY

Precise details of the date of onset of illness, presence, and distribution of such clinical features as rash, lymphadenopathy, and arthralgia should be obtained from pregnant women who present with rubella-like clinical features. If there is a history of contact with a rubella-like illness the date, duration, and type of contact (e.g. casual or more prolonged household contact) should be obtained, in order to interpret the results of virological investigations. In addition, enquiry should be made about results of previous screening tests for rubella antibodies and history of rubella vaccination.

Patients who have been exposed to rubella should be carefully followed up serologically because retrospective studies have shown that some women who delivered infants with CRS gave no history of a rubella-like illness during pregnancy. Blood should be collected from pregnant women with rubella-like features as soon as possible after the onset of symptoms. Provided that a blood sample is obtained within the first 3–4 days, it is usually possible to detect a significant rise in antibody concentration and rubella-specific IgM in a second blood sample taken a few days later.

Although most patients develop rubella antibodies within a few days of onset of symptoms, antibody responses may very occasionally be delayed for as long as 10 days. This underlines the importance of collecting further blood samples from patients who remain sero-

negative. Many patients present in the postacute phase of their illness, at which time antibody concentrations are likely to have reached maximum concentrations. It must be emphasized that there is no particular concentration of antibody ascertained by any test that can be regarded as indicative of recent or current infection. Because a virological diagnosis is usually required quickly for obstetric reasons, such patients should be tested for rubella-specific IgM with minimum delay.

Women who present within the incubation period and who have antibodies may be reassured, although it is often wise to obtain a second blood sample 7–10 days later to ensure that antibody concentrations are stable. The interpretation of results may depend on the accuracy of the history given by the patient. Sometimes an earlier blood sample is available (e.g. taken at the first antenatal visit) which can be tested in parallel with a sample taken after contact. If there is no change in antibody concentration the patient can be reassured with confidence that she was already immune.

Patients presenting after an interval greater than the incubation period and who are seropositive are more difficult to assess because antibody levels may already have reached their maximum. The sera of such patients should therefore be tested for rubella-specific IgM. Detection of rubella-specific IgM in women who give no history of a rubella-like rash or contact with such a rash, should be interpreted with caution. In some patients, the specific IgM may persist for months or years after infection and vaccination (Banatvala et al. 1985; Thomas et al. 1992) and false-positive results may occur in patients with autoimmune diseases and other infections. In such cases it is necessary to use further tests, such as specific IgG avidity and western blot to determine whether recent infection has occurred (Pustowoit and Liebert 1998; Thomas et al. 1999; Best et al. 2002).

Because rubella is unlikely to be acquired as a result of casual or brief contact (e.g. while shopping or in public transport), seronegative patients who experience this type of exposure should be reassured that the risks of acquiring rubella are small. Nevertheless, it is essential to follow up such people serologically. Those exposed more closely over a longer period are at greater risk, but even they may be reassured, particularly during nonepidemic times, by being told that the clinical diagnosis of rubella is often incorrect. Anxiety may be allayed by testing the index case, in order to confirm or refute the diagnosis. Patients who have been followed up, but who remain seronegative, should be offered rubella vaccination in the immediate postpartum period.

Laboratory diagnosis of congenital rubella

POSTNATAL TESTS

The National Congenital Surveillance Programme in the UK classifies suspected cases of congenital rubella according to the criteria listed in Table 4. The congenital rubella syndome (CRS) case classification for the United States has been revised (Reef et al. 2000).

A diagnosis of CRS can be established by:

- Detection of rubella-specific IgM in cord serum or serum samples obtained in early infancy. An IgM antibody capture assay is generally preferred for this purpose (Chantler et al. 1982; Hudson and Morgan-Capner 1996). Specific IgM has been detected by M-antibody capture radioimmunoassay (MACRIA) in all symptomatic infants up to the age of 3 months, in 90 percent of infants aged 3–6 months, in fewer than 50 percent of infants aged 6–12 months and only occasionally in children over 1 year old (Chantler et al. 1982). However, commercially available enzyme immunoassays (indirect and M-antibody capture formats) have not been evaluated for the diagnosis of CRS and may be less sensitive. The absence of specific IgM by IgM antibody capture assays in the neonatal period virtually excludes congenital rubella.
- Detection of persistent rubella IgG antibody in serum or oral fluid at a time when maternal antibodies are no longer detectable (approximately 8 months). This may be a useful technique when patients present too late for the detection of specific IgM.
- Isolation of RUBV or detection of RUBV RNA by RT-PCR (Bosma et al. 1995b) in specimens (such as pharyngeal swabs) taken from infants during early infancy. Facilities for RUBV isolation are not widely available. RT-PCR can also be applied to lens

Table 4 *Congenital rubella: case classification criteria (Miller et al. 1994)*

Congenital rubella infection	No rubella defects, but congenital infection confirmed by isolation of virus, or detection of specific IgM or persistent IgG in infant
Congenital rubella syndrome	
Confirmed	Typical rubella defect(s) plus virus-specific IgM or persistent IgG in infant; or two or more rubella defects plus confirmed maternal infection in pregnancy
Compatible	Two or more rubella defects with inconclusive laboratory data, or single rubella defect plus confirmed maternal infection in pregnancy
Possible	Compatible clinical findings with inconclusive laboratory data, e.g. single defect plus probable maternal infection in pregnancy
Unclassified	Insufficient information to confirm or exclude

aspirates from cataracts in order to establish a diagnosis of CRS (Bosma et al. 1995a).

RUBV can be isolated from the stools, urine, tears, CSF, and nasopharyngeal secretions of infants with CRS. Cooper and Krugman (1967) isolated RUBV from the nasopharynx of almost all severely infected infants at birth, but by the age of 3 months the proportion declined to about 60 percent and, by 9–12 months, to approximately 10 percent. Virus excretion has not yet been tested by RT-PCR, which may detect virus excretion for longer. However, RUBV may persist at other sites for even longer (see Persistence of virus). RUBV can be isolated from most of the organs obtained at autopsy from severely infected infants who die in early infancy. Babies excreting virus may transmit infection to susceptible contacts. Therefore, until virus is no longer being excreted, women of childbearing age, some of whom may be in the early stages of pregnancy, should be dissuaded from visiting such babies until serological tests confirm that they are immune.

Rubella-specific lymphoproliferative assays (O'Shea et al. 1992) and tests for low avidity specific IgG (Thomas et al. 1993) may be of value for retrospective diagnosis of CRS in children between the ages of 1 and 3 years.

Children with CRS may lose antibodies to the E1 glycoprotein (de Mazancourt et al. 1986; Mitchell et al. 1992b; Mauracher et al. 1993; Meitsch et al. 1997) and consequently HAI antibodies may not be detected (Cooper et al. 1971; Ueda et al. 1975). Forty-one percent of 40 persons with CRS tested at 60 years of age had no rubella antibodies detectable by EIA (Forrest et al. 2002). In order to determine the immune status of such persons in later life, it may be necessary to use tests such as western blot, which detect antibodies to individual RUBV polypeptides.

PRENATAL TESTS

Prenatal diagnosis of CRS may provide a more accurate estimate of risk when the mother is reluctant to have a therapeutic abortion following rubella in the first trimester, when maternal reinfection is confirmed or suspected and when serological results are equivocal, for example when rubella-specific IgM is detected in a woman with no history of a rubella-like illness. A prenatal diagnosis may be made by testing amniotic fluid for RUBV RNA by RT-PCR, and fetal blood for RUBV RNA and rubella-specific IgM. The detection of RUBV RNA in amniotic fluid and fetal blood has sensitivities of 87.5 percent and positive predictive values of 100 percent (Enders 1998) when tested by the RT-PCR method described by Bosma et al. (1995a). Amniotic fluid can be taken after 15 weeks' gestation and $\geqslant$8 weeks after onset of maternal rubella infection. However, as false-negative results may occur, it is desirable to test further amniotic fluid, as well as fetal blood at 22–23 weeks' gestation.

As the fetus may not produce sufficient IgM before 22 weeks' gestation, fetal blood should be obtained by cordocentesis after that time. It is advisable to test fetal blood for rubella-specific IgM with more than one assay as levels may be low. Although this approach means that the patient may have to wait some time for the final test, it is possible that false-negative results may be obtained before this time (Tang et al. 2003).

Prenatal diagnosis has also been discussed by Revello et al. (1997); Enders (1998) and Katow (1998).

PREVENTION

Rubella vaccination

Rubella and congenitally acquired rubella are preventable, and the elimination of CRS in some countries with national vaccination programs results from the administration of attenuated rubella vaccines.

RUBELLA VACCINES

The first attenuated strain of rubella was developed by the National Institutes of Health in the USA. This strain was isolated from a military recruit with acute rubella and attenuated by 77 passages in VMK cell cultures. Following preliminary trials in primates in which this vaccine was shown to be protective, controlled trials were conducted among institutionalized children, the vaccine strain having been passaged a further five times in duck embryo fibroblasts. Within a short time, further vaccine strains were prepared, being attenuated in primary rabbit kidney (Cendehill) and in human diploid cell cultures (RA27/3) (Proceedings 1969). The vaccine containing the RA27/3 strain, originally isolated from the fetal kidney of a rubella-infected conceptus, is the most widely used worldwide, although a number of vaccine strains developed in Japan and China are now used in these countries (Perkins 1985). The accumulated data from trials employing rubella vaccines show that they are immunogenic, protective, and well tolerated. Vaccinees excrete virus via the nasopharynx, but infection is not transmitted to susceptible contacts. The development and properties of different rubella vaccines have been reviewed by Banatvala and Best (1989) and Best (1991). Rubella vaccine is now usually given with measles and mumps vaccines as the triple vaccine measles, mumps, and rubella (MMR) (Salisbury and Begg 1996).

VACCINATION PROGRAMS

Rubella vaccines were licensed in the USA in 1969 and in the UK in 1970. In the USA a policy of universal childhood immunization was adopted, this being aimed at interrupting transmission of virus by vaccinating preschool children, thereby reducing the risk of pregnant women being exposed to rubella. Because high uptake

rates were achieved, this policy markedly reduced the incidence of postnatally acquired and CRS (Figure 8). However, in 1989/1990 rubella occurred among unvaccinated women in some parts of the USA, resulting in cases of CRS (Lindegren et al. 1991). Rubella vaccine is now given as the MMR vaccine at 12–15 months and 4–6 years of age. Those who miss the second dose should be offered it at 11–12 years (Centers for Disease Control and Prevention 2001a).

A selective vaccination program was initially adopted in the UK, this being directed first at prepubertal schoolgirls, women at particular risk of acquiring rubella (e.g. nurses and school teachers), and seronegative adult women identified by rubella antibody screening. Because complete vaccination of the target population was an unrealistic goal, the vaccination program was augmented in 1988 by offering rubella vaccine to preschool children of both sexes (Banatvala 1987) and rubella is now given with measles and mumps (MMR) vaccine in two doses at 12–15 months and 4–5 years of age. This resulted in a fall in the number of reported cases of rubella, congenital rubella, and of terminations of pregnancy because of rubella (Figure 9). Following the administration of MR vaccine to all 5- to 16-year-old school children in late 1994 to prevent a predicted measles epidemic, it was agreed to discontinue vaccination of schoolgirls, but to continue to ensure that susceptible pregnant women were vaccinated postpartum.

Although a significant proportion of young adult males remains susceptible, high rates of vaccine uptake among preschool children together with the markedly reduced susceptibility among pregnant women have resulted in CRS being rare in the UK. Thus, in contrast to 1984 in which 52 cases were reported, in 1996 only 12 cases were notified to the National Congenital Rubella Surveillance Programme. Two of the 12 mothers had acquired the infection while abroad (Tookey and Peckham 1999). Seven babies with CRS were born in the 2-year period 2000–2001. Five of the seven mothers had acquired rubella abroad (Rahi et al. 2001; P Tookey, personal communication, 2002). It will be unfortunate if CRS returns in the future, as a consequence of the fall in the uptake of MMR due to the unjustified public concern about its safety (see Vaccine reactions).

Most countries in Europe administer MMR vaccine between the first and second birthdays; and many now offer a second dose. Although uptake of rubella vaccine is poor in some countries in Europe, Sweden and Finland have eliminated rubella by use of two-dose MMR programs (Peltola et al. 1994; Böttiger and Forsgren 1997). A review published by the World Health Organization (WHO) in 1997 highlighted the problem of congenital rubella in developing countries (Cutts et al. 1997). A meeting was held in 2000 to consider methods for surveillance of rubella and congenital rubella and the use of rubella vaccines in developing countries (World Health Organization 2000a). WHO also published guidelines for the surveillance of rubella and CRS (World Health Organization 1999) and a position paper on rubella vaccines (World Health Organization 2000b). Many developing countries have introduced rubella vaccination, since it has been shown to be cost-effective (Hinman et al. 2002), and by 2002, 123 (57 percent) of all countries/territories in the world had included rubella vaccination in their national immunization programs (Figure 10). Forty-one of the 44 countries in the Pan American Health Organization (PAHO) had incorporated MR or MMR into their childhood immunization programmes by 2002 (World Health Organization 2003a). Although it is desirable to give rubella vaccine to children with measles (as MR or

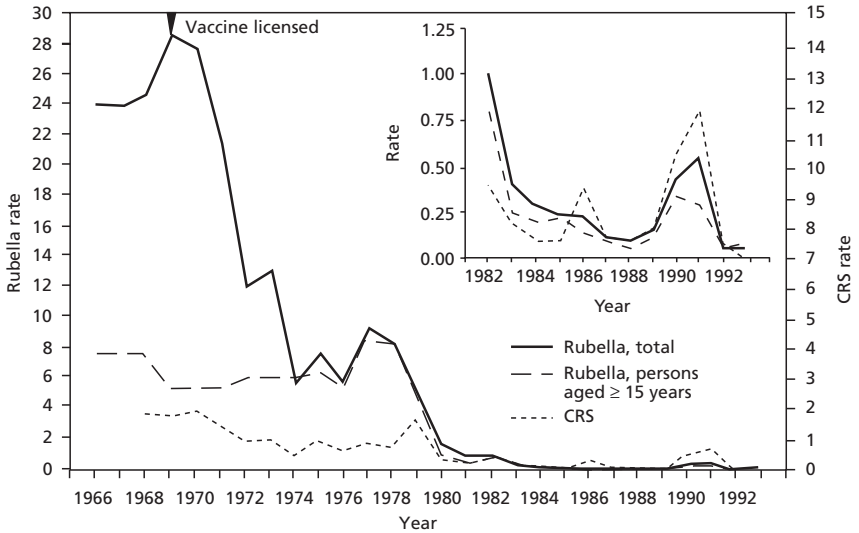

Figure 8 *Incidence rates of rubella and congenital rubella syndrome (CRS) in the USA, 1966–1993; cases of rubella reported to the National Notifiable Disease Surveillance System per 100 000 population; cases of CRS reported to the National CRS Registry per 100 000 live births (from Centers for Disease Control and Prevention, 1994).*

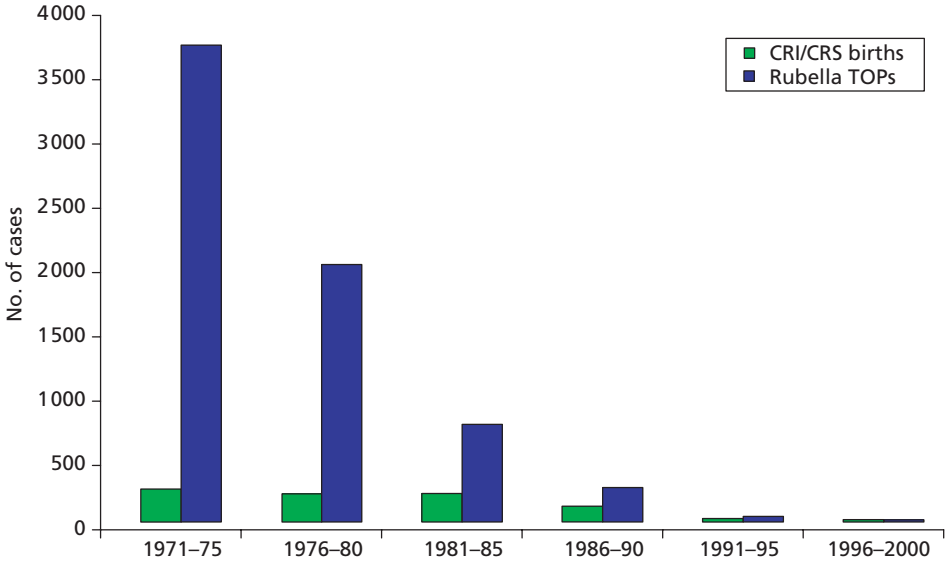

Figure 9 *Congenital rubella births and rubella-associated terminations of pregnancy (TOP) in England and Wales (data from National Congenital Rubella Surveillance Programme 2003, www.ich.ucl.ac.uk).*

MMR), it is also necessary to vaccinate susceptible women of child-bearing age, as childhood vaccination alone will increase the risk to susceptible adults (Robertson et al. 1997, World Health Organization 2000a, c). WHO recommend that surveillance for rubella, CRS, and rubella vaccine coverage should be monitored (World Health Organization, 1999, 2003a), since it is necessary to have a vaccine uptake of at least 80 percent among children to prevent circulation of rubella.

IMMUNE RESPONSES

About 95 percent of vaccinees develop an immune response. Serum antibodies develop between 10 and 28 days after vaccination and reach maximum levels about 6 months later. Occasionally, antibody responses may be delayed for up to 8 weeks. Failure to respond may result from concurrent infections, pre-existing low levels of antibody undetectable by less sensitive assays, or the presence of passively acquired antibody acquired maternally, via blood transfusion or administration of immunoglobulin. Failure to comply with the manufacturer's recommendations during storage or after reconstitution may result in virus inactivation and loss of potency of the vaccine.

Following vaccination, antibodies to the major structural proteins E1, E2, and C may be detected, and rubella-specific IgG, IgA and IgM responses are present. Specific IgM responses are detected in about 70 percent of vaccinees. Occasionally, rubella-specific IgM may persist at low levels for up to 4 years after vaccination (O'Shea et al. 1985). Virus-specific IgA concentrations decline more rapidly than specific IgG. There is a transient oligomeric (10S) IgA response, which is succeeded by a 7S response that may persist at low levels for 10–12 years after vaccination. The RA27/3 vaccine induces a secretory IgA response which persists for up to 5 years (O'Shea et al. 1985).

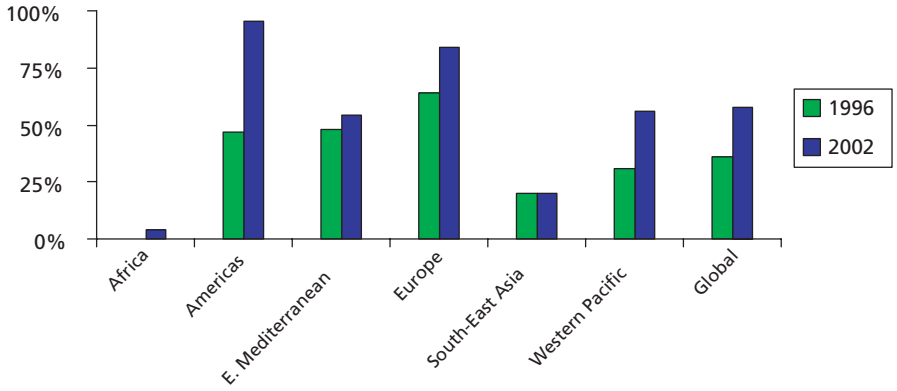

Figure 10 *Percentage of countries/territories, by WHO region and globally, with rubella vaccine in the national immunization system, 1996 and 2002 (Source: WHO Department of Vaccines and Biologicals, December 2002).*

Although serum antibody levels detected by HAI and SRH persist for at least 21 years in most vaccinees, in approximately 10 percent the levels decline to <15 IU/ml within 5–8 years. A small number may become completely seronegative (reviewed by Banatvala and Best 1989). However, when volunteers with low levels of antibody were challenged intranasally with high titer RA27/3 vaccine, most appeared to be protected although a transient low level of virus-specific IgM was present in four of 19 and a transient viremia was detected in one of 19 volunteers (O'Shea et al. 1983). A transient lymphoproliferative response has been detected following rubella vaccination (Buimovici-Klein and Cooper 1985).

VACCINE EFFICACY AND RE-INFECTION

The protective efficacy of rubella vaccines is about 95 percent (reviewed by Plotkin 1999). Experimental studies demonstrate that reinfection (see relevant sections on reinfection) is more likely to occur in those whose immunity is vaccine-induced than in those with naturally acquired immunity (reviewed by Best 1991). Re-infection is less likely to occur after vaccination with the RA27/3 vaccine strain, than with the Cendehill and HPV-77 vaccine strains, which is why the RA27/3 strain is now used in most rubella vaccines (see above).

Vaccination is recommended for adult women who have rubella antibodies <10 IU/ml, but some of these women will fail to mount a booster response, as seen in vaccine trials (Best 1991). Therefore, no more than two doses of vaccine are indicated for such women. However, it may be of value to test the sera from these women for rubella IgG using more than one technique (Best, 1991; Best and O'Shea 1995). Following vaccination, women may be considered immune if antibodies $\leqslant$10 IU/ml are detected by two different techniques. Survivors of CRS may fail to respond to rubella vaccine.

VIRUS EXCRETION

Rubella vaccine may be detected in nasopharyngeal secretions from most vaccinees 6–29 days after vaccination, as well as in the breast milk of lactating women vaccinated postpartum. Although lack of transmission to susceptible contacts may result from low concentrations in nasopharyngeal secretions, it is possible that attenuation may alter the biological properties of the virus, resulting in poor replication in the respiratory tract. Very occasionally, virus has been transmitted to breastfed infants, but they do not develop any clinical features of infection.

VACCINE REACTIONS

Rubella vaccine is well tolerated although lymphadenopathy, rash, and arthropathy may occur between 10 and 30 days after vaccination. In general, such reactions are less severe than following naturally acquired infection. Indeed, vaccinees may fail to notice their lymphadenopathy and, if rash occurs, it is usually macular, faint, and evanescent. Joint symptoms are related to age and gender, being rare in children of both sexes (2.5–10 percent), but occurring in up to 58 percent of post-pubertal females. Most commonly, the small joints of the hands are affected, but the knees, wrists, and ankles may also be involved. Symptoms rarely persist for longer than a week. However, a small proportion of vaccinees may develop arthritis with pain and limitation of joint movement, which may occasionally recur intermittently. Joint symptoms rarely result in absence from work.

Although it has been suggested that MMR is associated with inflammatory bowel disease and autism, several longitudinal studies have failed to confirm an increased incidence among MMR vaccinees. A number of prestigious groups and committees have examined the evidence and stated that there is no good scientific evidence to support this theory (Chief Medical Officer 2001; Institute of Medicine 2001; Miller, 2001; World Health Organization 2003b). The association is circumstantial as these diseases are first detected at about 15 months of age, the age at which MMR is given to children. However, due to the publicity generated in the media, public concern has resulted in a serious fall in the uptake of MMR in some parts of the UK, which has lead to outbreaks of measles (Jansen et al. 2003).

CONTRAINDICATIONS

As with other live vaccines, immunocompromised patients should not be vaccinated. Such people include those with malignant disease and those being treated with cytotoxic drugs, radiotherapy, or corticosteroids. Thrombocytopenic patients should not be vaccinated. HIV-positive people, with or without symptoms, are exceptions to these recommendations because they may be vaccinated with such live vaccines as MMR and polio. HIV-positive people do not react adversely to such live vaccines but, if unprotected, may experience serious complications, particularly if infected with measles.

Live vaccines may be administered concurrently, preferably at different sites (except in the case of MMR). If this is not possible, the two live vaccines should be separated by an interval of 3 weeks. A similar period should be allowed between the administration of rubella vaccine, or MMR, and BCG. If a vaccinee has a febrile illness, it is prudent to postpone rubella vaccination until the individual has recovered. The rubella vaccines may contain such antibiotics as neomycin, kanamycin, or polymyxin, and anyone with established hypersensitivity to these antibiotics should not be vaccinated. As passively acquired antibodies may interfere with vaccine-induced responses, rubella vaccination

should be delayed for 3 months after blood transfusion or administration of immunoglobulin. However, the administration of anti-D immunoglobulin does not suppress vaccine-induced immune responses, although it may be prudent to confirm seroconversion 2–3 months after vaccination.

VACCINATION DURING PREGNANCY

Although wild-type strains of rubella are teratogenic, the accumulated data from studies reported in different countries, in which 661 rubella-susceptible women were vaccinated during pregnancy, have shown that this has not resulted in rubella-induced permanent fetal defects. Forty-four percent of these women were vaccinated during the high-risk period between 2 weeks before and 6 weeks after conception. Vaccine strains may, however, infect the conceptus because rubella vaccine strains have been isolated from the placenta, kidney, and bone marrow for up to 94 days after vaccination. Furthermore, rubella-specific IgM responses or antibodies persisting for up to a year have been detected in about 3 percent of infants delivered of mothers inadvertently vaccinated during early pregnancy. Among the 661 infants born to women who were inadvertently vaccinated during pregnancy, only one rubella-IgM positive infant had a heart murmur which resolved by 2 months of age (P. Tookey, personal communication 2000; reviewed by Best and Banatvala 2004).

The theoretical maximum risk of rubella vaccine-induced major malformations based on a 95 percent confidence limit of the binomial distribution has been calculated to be 1.2 percent, this being less than the 3 percent of major malformations occurring in 'normal' pregnancies (Bart et al. 1985; Enders 1985). These encouraging reports have resulted in a substantial reduction in terminations of pregnancy being carried out as a result of inadvertent vaccination in pregnancy in Britain. Nevertheless, it is still recommended that pregnant women should not be vaccinated against rubella and that pregnancy should be avoided for 1 month after vaccination (Salisbury and Begg, 1996; Centers for Disease Control and Prevention 2001b).

Passive immunization

Normal human immunoglobulin does not confer any clearcut protection (Report 1970). This preparation may reduce the incidence of clinically overt maternal infection, but subclinical infection may nevertheless occur, with a prolonged incubation period. Because inapparent infection is accompanied by viremia, fetal damage is not prevented when it is used in pregnancy. However, it is possible that the administration of normal human globulin reduces the level of fetal infection or damage, or both (Peckham 1974; Hanshaw et al. 1985).

High-titer rubella immunoglobulin has been used experimentally to determine whether infection induced by rubella vaccine can be prevented (Urquhart et al. 1978). This preparation has not been properly evaluated in the field, but may be recommended for the few susceptible pregnant women who come into contact with clinical rubella and for whom therapeutic abortion is unacceptable.

Flaviviruses

JOHN T. ROEHRIG AND DUANE J. GUBLER

Properties of the viruses	1	Tick-borne infections	11
Clinical and pathological aspects	5	*Pestivirus* infections	12
Important mosquito-borne diseases	7	References	13

PROPERTIES OF THE VIRUSES

This family of enveloped, positive-strand RNA viruses contains over 70 members, of which about 50 are arthropod-borne; many are pathogenic for humans and other vertebrates. The family name is derived from that of the type species, *Yellow fever virus* (YFV) (Latin: *flavus* = yellow).

Classification

The family *Flaviviridae* contains three genera: *Flavivirus*, *Pestivirus*, and *Hepacivirus*, and the unassigned GBV viruses (GBV-A, GBV-B, and GBV-C). All members of the *Flavivirus* genus are antigenically related. Serological crossreactions are most evident in hemagglutination-inhibition (HI) tests, and plaque reduction neutralization tests (PRNT) show the greatest specificity. Seven subgroups or complexes of flaviviruses have been defined on the basis of cross-neutralization tests (De Madrid and Porterfield 1974), and this subdivision has recently been substantially confirmed and extended in a more comprehensive study (Calisher et al. 1989). Flaviviruses can also be divided into three biological subsets based upon their mode of transmission, by mosquitoes, ticks, or by having no known arthropod vector. Table 1 shows the relationship between the subgroups determined by the PRNT and the mode of transmission of currently named flaviviruses.

Three pathogens of farm animals: hog cholera virus (HCV) or *Classical swine fever virus* (CSFV), bovine viral diarrhea virus (BVDV), and *Border disease virus* (BDV), constitute the *Pestivirus* genus. The mosquito cell-fusing agent is an additional member of the *Flaviviridae* but is outside the genus *Flavivirus*. Hepaciviruses as well as the unassigned GBV viruses, both agents of hepatitis, are the topic of another chapter and are not further discussed here.

Morphology and virion structure

Flaviviruses possess an isometric core, 30–35 nm in diameter, that contains a nucleocapsid or core (C) protein complexed with single-stranded positive-sense RNA. This core is surrounded by a lipid bilayer containing an envelope (E) protein and a membrane (M) protein, giving a total virion diameter of about 45 nm. The flavivirus E protein is a class II fusion protein. The M protein is first synthesized as a precursor protein, prM. The virion structure of dengue virus (DENV) virus has recently been solved using cryo-electron microscopy, and differs from the structure of recombinant subviral particles (RSP) derived from mammalian cells transfected with a plasmid containing only the genes for the prM and E proteins of tick-borne encephalitis virus (TBEV) (Ferlenghi et al. 2001; Kuhn et al. 2002). The virion envelope contains an icosahedral scaffold of 90 E protein dimers (Kuhn et al. 2002).

Pestiviruses are 40–60 nm particles that contain an electron-dense core of about 30 nm. The virion is enveloped with the E^{rns}, E1, and E2 proteins associated with envelope. Purified pestiviruses sometimes show a racquet type of morphology (Renard et al. 1985).

Genome structure and function

The genome of flaviviruses is a molecule of single-stranded, positive-sense RNA, approximately 11 kb in

length containing short untranslated regions at 3′ and 5′ ends, a 5′ cap and a non-polyadenylated 3′ terminus (Figure 1). There is no subgenomic mRNA in flavivirus-infected cells. Complete genome sequences are known for YFV (Rice et al. 1985; Chambers et al. 1989), West Nile virus (WNV) (Castle et al. 1985; Wengler et al. 1985, 1987; Nowak et al. 1989; Lanciotti et al. 1999), all four serotypes of DENV (Hahn et al. 1988; Mackow et al. 1987; Osatomi and Sumiyoshi 1990; Fu et al. 1992), Japanese encephalitis virus (JEV) (Sumiyoshi et al. 1987), Kunjin virus (KUNV) (Coia et al. 1988), Powassan virus (POWV) (Mandl et al. 1993) and TBEV (Pletnev et al. 1990). A number of partial genome sequences, primarily of the E proteins,

U, unrelated to any other virus.
a) Batu Cave virus, Potiskum virus, and *Yaounde virus* were not examined in either series, but are included for completeness.

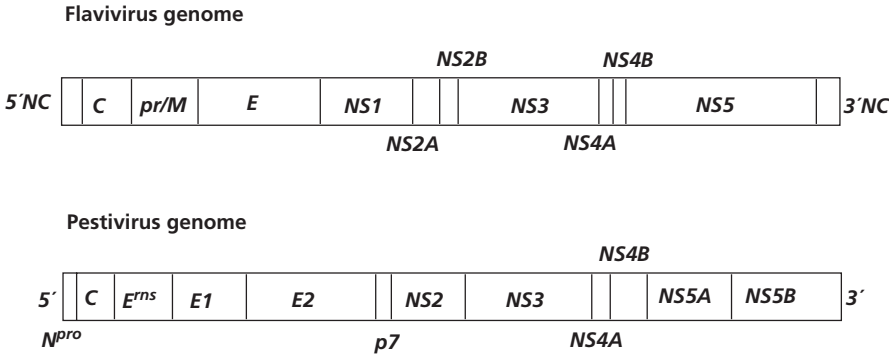

Figure 1 *Flavivirus and Pestivirus genome organization.*

are also available. A single long open reading frame (10 223 nt in the case of YFV) spans almost the entire length of the RNA. The gene order is 5′-*C–prM–(M)–E–NS1–NS2A–NS2B–NS3–NS4A–NS4B–NS5*-3′ (Rice et al. 1985) (Figure 1).

The genome of pestiviruses has been shown to be more similar to hepaciviruses than flaviviruses and is reported to be 12.5 kb in length. The 3′ end of the genomic RNA is not polyadenylated (Renard et al. 1987), and unlike flaviviruses, the pestivirus RNA lacks a 5′-cap structure (Brock et al. 1992). The pestivirus genome encodes a single open reading frame with a theoretical coding capacity of about 4 000 amino acids. Complete genome sequences have been determined for CSFV (Meyers et al. 1989; Moormann et al. 1990) and BVDV (Collett et al. 1988; Deng and Brock 1992), and BDV (Becher et al. 1994, 1998). Similar to flaviviruses, the genes encoding the structural proteins are located at the 5′ end of the genome. The gene order is 5′-*Npro–C–Erns–E1–E2–p7–NS2–NS3–NS4A–NS4B–NS5A–NS5B*-3′ (Collett et al. 1989).

Polypeptides: structural and nonstructural

Cell-associated flaviviruses have a C protein with a molecular mass of 12–13 kDa surrounded by a lipid bilayer containing the two membrane glycoproteins E and prM (mol. mass 50 and 22 kDa, respectively). Extracellular virions contain the shorter M protein (mol. mass 8 kDa) instead of prM. Seven nonstructural proteins have been well described (see section below on Replication). Because of the continued medical significance of the flaviviruses, the structure and function of the E protein (approximately 500 amino acids) have been intensely investigated.

Three antigenic domains (A, B, and C) have been identified on the E protein (Mandl et al. 1989; Heinz and Roehrig 1990; Roehrig et al. 1998). The A domain (amino acids 50–130 and 185–300) is a linearly discontinuous domain that is divided by the C domain (amino acids 130–185). The A-domain structure is stabilized by five disulfide bridges and contains mostly conformationally dependent virus-neutralizing epitopes. Much of the antigenicity of the B domain (amino acids 300–400) requires a disulfide bond between Cys 11 and Cys 12. The A, B, and C domains constitute the ‘head’ of the E glycoprotein. A 100 amino acid stalk (approximately amino acids 400–500) that includes a 50 amino acid hydrophobic tail (amino acids 450–500) anchors the molecule in the virion envelope. Unlike other enveloped viruses, there is essentially no cytoplasmic tail on the E protein. The three-dimensional molecular structure of the amino terminal 380 amino acid tryptic fragment of the TBEV E protein homodimer has recently been solved (Rey et al. 1995). The protein folds into three distinct domains (I, II, and III), which correlate well to the previously defined domains C, A, and B. Because the locations of the E protein Cys residues are conserved among all flaviviruses, it is generally assumed that this overall structure is the same for all flaviviruses (Figure 2).

Three major nonstructural proteins (NS1, NS3, and NS5) can be found in flavivirus-infected cells. The NS1 protein is a membrane-bound glycoprotein whose function has not been fully determined. It is possible that this protein is involved in virion morphogenesis. The NS2A and NS3 proteins appear to function in concert as a virus-specific protease (Yusof et al. 2000; Leung et al. 2001). The NS3 protein also exhibits helicase activity (Utama et al. 2000; Matusan et al. 2001). The crystal structure of a portion of the NS3 proteins has recently been solved (Valle and Falgout 1998; Krishna Murthy et al. 1999; Murthy et al. 1999, 2000). The NS5 protein is the virus RNA-dependent RNA-polymerase.

Pestivirus proteins also appear to be synthesized as a polyprotein. Four structural proteins: C (14 kDa), and three envelope proteins – E^{rns} (44–48 kDa), E1 (33 kDa), and E2 (55 kDa) – have been identified. The envelope glycoproteins, E1 and E2, form dimers through disulfide bridging in both infected cells and virions. The nonstructural protein N^{pro} (23 kDa) that has autoproteolytic activity is located 5′ of the C protein. This protein has no analogue in the flaviviruses. Pestiviruses also do not

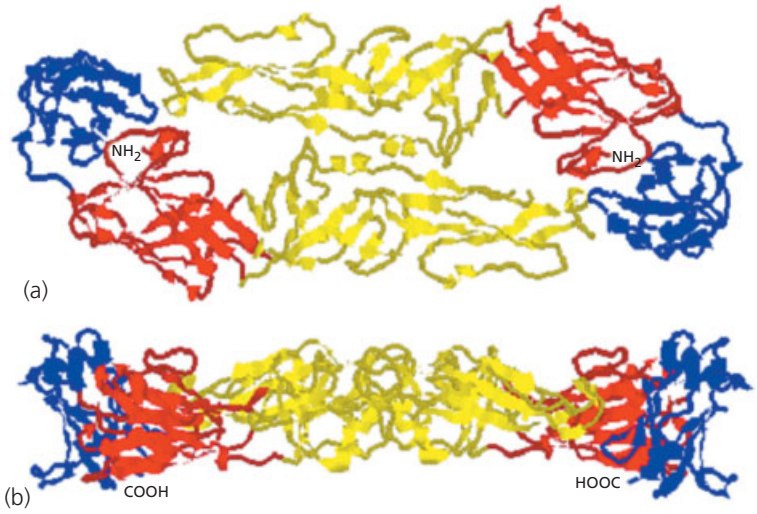

Figure 2 *E-glycoprotein structure. Homodimer of the TBE E protein (a.a. 1–395). Color domains: Domain I (C-domain), red; Domain II (A-domain), yellow; Domain III (B-domain), blue.* **(a)** *top view;* **(b)** *side view.*

appear to have a protein analogue of the flavivirus NS1 protein. Another nonstructural protein, NS2/NS3, is located 3′ of the envelope genes and apparently functions as a viral protease involved in polyprotein processing (Wiskerchen and Collett 1991). The NS2/NS3 protein is cleaved to NS2 and NS3 in some pestiviruses. Both the NS2/NS3 and the cleaved NS3 must have serine protease activity, even though the catalytic motif is located in the N-terminal region of NS3. At least three other nonstructural proteins have been identified: NS2, NS5A, and NS5B. The NS5B contains sequence motifs similar to flaviviral RNA polymerase.

Antigens

The E protein is the viral hemagglutinin, which also elicits neutralizing, enhancing, and protective antibodies. The C protein contributes to the group reactivity detected by the complement fixation (CF) test. The NS1 protein is responsible for inducing the soluble complement-fixing antigen detected in virus-infected cells. Monoclonal antibodies (mAb) specific for the NS1 protein can protect animals from virus challenge (Schlesinger et al. 1987; Henchal et al. 1988; Zhang et al. 1988; Falgout et al. 1990; McCown et al. 1990).

The pestivirus E^{rns} and E2 are primarily responsible for eliciting pestivirus neutralizing antibodies (Weiland et al. 1990, 1992). Because it is difficult to elicit virus-neutralizing antibody specific for the E1 protein, it is thought that most of this protein is buried in the virus envelope, similar to the flavivirus M protein.

Replication

Although it has not been conclusively proven, evidence is accumulating that flaviviruses infect cells by attaching to cellular receptors through the E-protein domain III (Bhardwaj et al. 2001; Crill and Roehrig 2001; Hurrelbrink and McMinn 2001). Flavivirus cellular receptor moieties have been implicated but not been identified conclusively (Chen et al. 1997; Lee and Lobigs 2000, 2002; Chu and Ng 2002; Germi et al. 2002). After endocytosis, the nucleocapsid is released into the cytoplasm by membrane fusion catalyzed by a low-pH dependent conformational change in the E protein. All flavivirus E proteins have a highly conserved sequence (amino acids 98–110) that has chemical similarities to regions shown to be responsible for cell-membrane fusion in orthomyxoviruses and paramyxoviruses.

The viral mRNA is translated as a polyprotein, which undergoes extensive co-translational and post-translational proteolytic processing and cleavage by cellular signalase(s). Cleavage generates the primary amino acid sequence of the mature structural proteins, prM and E, and the amino terminus of the following nonstructural protein, NS1. The amino-terminal portion of the polyprotein is released as a molecule, the anchored C protein, which is associated with membranes of the rough endoplasmic reticulum. The anchored C protein is converted to mature C protein by removal of the carboxyl-terminal hydrophobic segment. Cell-associated virions are constructed from the proteins C, prM, and E. The prM protein is cleaved in the Golgi vesicles, by a furin-like enzyme resulting in loss of the amino-terminal fragment of this protein and release of mature virions from infected cells. It is currently believed that the prM protein functions as an E-protein chaperone, protecting it from acid-catalyzed denaturation during virus maturation. The cleavage sites generating the nonstructural proteins NS2A, NS2B, NS4A, and NS4B have been identified.

Flavivirus infection causes virus-specific cytopathic effects in mammalian cells. Flavivirus cell killing has recently been identified as an apoptotic event (Despres et al. 1996, 1998; Liao et al. 1997, 1998; Marianneau et al. 1997, 1998a, b, c, 1999; Avirutnan et al. 1998; Couvelard et al. 1999; Kamalov et al. 1999; Balachandran et al. 2000; Jan et al. 2000; Matthews et al. 2000; Ho et al. 2001; Prikhod'ko et al. 2001, 2002; Su et al. 2001, 2002; Lin et al. 2002; Parquet et al. 2002; Sauerwald et al. 2002; Shafee and AbuBakar 2002). Cytopathic effects in flavivirus-infected arthropod cells are not as dramatic. The site of flavivirus budding is not fully defined. Nucleocapsids do not appear to accumulate at the plasma membranes, indicating that budding may be quite efficient.

The processing of the pestivirus structural proteins has been described (Rümenapf et al. 1993). The pestiviral envelope glycoproteins are produced as a precursor protein, E^{rns}/E1/E2, which is rapidly cleaved to E^{rns}/E1 and E2. The E^{rns}/E1 precursor is then processed to E^{rns} and E1. The E^{rns} protein has no hydrophobic anchor sequence and can be found in infected cell supernatant. This cleavage pattern is similar to that seen with the flavivirus prM/E protein.

Flavivirus vaccines

The live-attenuated YFV vaccine is historically one of the most successful virus vaccines ever developed. It has low reactogenicity and excellent immunogenicity. Recently, however, a low rate of both neurotropic and viscerotropic adverse reactions following vaccination with YFV vaccines have been documented (Vasconcelos et al. 2001; Cetron et al. 2002). These reactions have primarily been associated with vaccination of the elderly, and preliminary genomic sequence data from recovered YFV vaccine show no signs of reversion. Further study is necessary to determine the reasons behind these new observations.

Modern approaches based on recombinant DNA technology are now being applied to flavivirus vaccine development. These approaches utilize DNA copies of the viral genome or individual viral genes to prepare either attenuated chimeric flaviviruses or direct DNA vaccines. Chimeric viruses based on either the YFV or DENV genome have been prepared (Bray and Lai 1991; Guirakhoo et al. 1999, 2000, 2001, 2002; Monath et al. 1999, 2000, 2002; Butrapet et al. 2000; Huang et al. 2000; Arroyo et al. 2001). Some of these chimeric vaccines have passed preclinical testing and are being prepared for human clinical trials. DNA-based vaccines have been prepared from number of flaviviruses (Konishi et al. 1997, 2000a, b, 2001; Chang et al. 2000, 2001; Hunt et al. 2001; Konishi and Fujii 2002). Preliminary tests of a DNA vaccine for WN virus have suggested that it may be effective in horses (Davis et al. 2001).

CLINICAL AND PATHOLOGICAL ASPECTS

Diseases caused by flaviviruses: general features

The flaviviruses known to cause human disease are listed in Table 2, several of which may also cause disease in wild or domestic animals. For example, in South Africa, Wesselsbron virus (WESSV) causes disease in sheep, and to a lesser extent goats and cattle (Coetzer and Theodoridis 1982); Kyasanur Forest disease virus (KFDV) has killed monkeys in India (Sreenivasan et al. 1979); and YFV can kill South American monkeys in nature and Asian monkeys in the laboratory, but not African monkeys. Israel turkey meningo-encephalitis virus (ITV) has caused economic losses in turkey farms in Israel and is also present in South Africa (Barnard et al. 1980).

CLINICAL MANIFESTATIONS

Flaviviruses cause a spectrum of clinical manifestations ranging from asymptomatic infections to undifferentiated febrile illnesses, fevers with rash or arthralgia or both, to hemorrhagic fevers, hepatitis, and encephalitis, which may result in death. The same virus can cause a variety of syndromes.

ARTHROPOD VECTORS

Much is known about the epidemiology of viruses such as DENV, YFV, JEV, St. Louis encephalitis virus (SLEV), and Central European TBEV, but there are also many uncertainties about these and other flaviviruses. For example, there are substantial differences between the natural history of YFV in Africa and in the New World (Downs 1982). YFV and DENV are classic examples of mosquito-borne flaviviruses, being transmitted in urban outbreaks by *Aedes aegypti* in both Africa and the Americas (YFV) and globally in the tropics (DENV) by a variety of mosquito species in the forest cycle. DENV are the only arboviruses that have fully adapted to a human–mosquito–human cycle and no longer depend on the forest cycle for maintenance. It has also been recovered from ticks in West Africa (Germain et al. 1982), although it is not known whether these arthropods contribute to the maintenance of the virus in nature.

In general, mosquito-borne flaviviruses are more common in the tropics, whereas tickborne flaviviruses tend to be prevalent in more temperate regions. The flaviviruses without a known vector are associated with rodents and bats, and are thought to be transmitted by contact with infective secretions. Only one virus in this subset, Dakar bat virus (DBV), is known to infect humans naturally, but several other nonvector-borne flaviviruses have caused laboratory infections. Transovarial, vertical,

Table 2 *Flaviviruses known to cause human disease*

Virus	Geographical distribution	Other features
Mosquito-borne viruses		
Banzi virus (BANV)	S and E Africa	2 cases only
Bussuquara virus (BSQV)	Brazil, Colombia, Panama	1 case only
Dengue viruses 1–4 (DENV types 1–4)	Worldwide in the tropics	Tropics and subtropics where the virus and a *Stegomyia* vector exist
Edge Hill virus (EHV)	Australia	
Ilhéus virus (ILHV)	C and S America	
Japanese encephalitis virus (JEV)	E, SE, S Asia, W Pacific	
Kedougou virus (KEDV)	Africa	Laboratory infection
Kokobera virus (KOKV)	Australia	
Kunjin virus (KUNV)	Australia, Sarawak	
Murray Valley encephalitis virus (MVEV)	Australia, New Guinea	
Rocio virus (ROCV)	Brazil	Epidemics of encephalitis
St. Louis encephalitis virus (SLEV)	N America, Panama, Jamaica, Trinidad, Brazil, Argentina	
Sepik virus (SEPV)	New Guinea	1 case only
Spondweni virus (SPOV)	E, W & S Africa	
Usutu virus (USUV)	E, W, Central Africa, Central Europe (Austria)	Found in birds in Austria
Wesselsbron virus (WESSV)	E, W, S Africa, Thailand	
West Nile virus (WNV)	E, W, S Africa, S and SE Asia, India, Mediterranean area, N America	Large epidemic throughout USA
Yellow fever virus (YFV)	W and Central Africa, S and Central America	Periodical epidemics, e.g. Ethiopia, Nigeria
Zika virus (ZIKV)	E and W Africa, Malaysia, Philippines	1 case in Uganda
Tickborne viruses		
Absettarov virus (ABSV)	Europe	
Hanzalova virus (HANV)	Europe	
Hypr virus (HYPRV)	Europe	
Karshi virus (KSIV)	Asia	
Koutango virus (KOUV)	Africa	
Kumlinge virus (KUMV)	Europe	
Kyasanur Forest disease virus (KFDV)	Mysore, India	
Langat virus (LGTV)	Malaysia	Only experimental cases proven
Louping ill virus (LIV)	British Isles	
Negishi virus (NEGV)	Asia	
Omsk hemorrhagic fever virus (OHFV)	The former Soviet Union	
Powassan virus (POWV)	Canada and USA	
Tick-borne encephalitis		
Western equine encephalomyelitis virus (WEEV)	Europe from Scandinavia to Balkans and from Germany to the former Soviet Union	
Eastern equine encephalomyelitis virus (EEEV)	Eastern Europe and the former Soviet Union	
No known arthropod vector		
Apoi virus (APOIV)	Japan	Laboratory infection
Dakar bat virus (DBV)	W, E and Central Africa, Madagascar	2 cases only
Phnom Penh bat virus (PPBV)	Cambodia, Malaysia	
RBV	USA, Mexico	

and trans-stadial transmission have been documented with several mosquito-borne and tickborne flaviviruses (Rosen 1987).

PATHOGENESIS

Flavivirus infections in humans cause three main disease patterns – nonspecific febrile illness (pantomorphic), encephalitis (neuromorphic), and hemorrhagic fever (viseromorphic) – which generally reflect the tropisms of the viruses for different target organs (Monath 1986). Symptoms in most flavivirus infections probably result from the direct effects of virus replication in the various target organs, which include the brain, liver, skin, lymphoid tissue, and cells of the mononuclear phagocyte lineage. Most flaviviruses are pantomorphic, causing only a nonspecific febrile illness in a large proportion of infections. Some, however, have virulence and evolutionary host characteristics that make them more neuromorphic or viseromorphic, thus causing encephalitis or hemorrhagic fever, respectively.

Both viral and host factors influence the pathogenesis of flaviviral infections of humans. Many flaviviruses have been shown to vary naturally in virulence characteristics as a result of selection pressures associated with the arthropod vector and/or vertebrate host. In addition, host factors such as age, immune status, and genetic background may influence pathogenesis. A mouse model of natural resistance to flavivirus infection has been developed (Brinton et al. 1998; Sangster et al. 1998; Shellam et al. 1998; Brooks and Phillpotts 1999; Urosevic et al. 1999; Silvia et al. 2001; Mashimo et al. 2002; Perelygin et al. 2002). This resistence appears to be associated, at least in part, with the intrinsic antiviral interferon response.

IMMUNE RESPONSE

Antigenically related flaviviruses may co-exist within similar habitats. There is extensive crossreactivity between flaviviruses in serological tests, and while there is no cross-protective immunity, heterologous flavivirus antibody may modulate clinical illness. This is especially important with DENV, in that infection with a single serotype provides homotypic immunity, but may enhance infection with a heterologous DENV and increase the risk of dengue shock syndrome (DSS) or dengue hemorrhagic fever (DHF).

DIAGNOSIS

Isolation of virus provides definitive evidence of flavivirus infection. Development of rapid and sensitive assays to detect viral RNA in tissue have extended the abilities to identify virus when viral titers are too low for isolation, or specimens have not been handled properly (Briese et al. 2000; Lanciotti et al. 2000; Lanciotti and Kerst 2001; Hunt et al. 2002; Komar et al. 2002). In practice, however, infections are diagnosed most frequently on the basis of serological tests, which include the PRNT, CF, and HI, and ELISA for virus-specific IgM and IgG (Roehrig 2000). A variety of flavivirus derived murine mAbs are available for virus identification (Roehrig 2000).

CONTROL

Measures directed towards vector control provide the only practical means of limiting virus transmission for most flaviviruses. Vaccines are available for YFV, JEV, and TBEV.

IMPORTANT MOSQUITO-BORNE DISEASES

Yellow fever virus

Although yellow fever virus (YFV) is believed to have originated in Africa, the first recorded outbreak was in Mexico in 1648. This was followed during the seventeenth, eighteenth, and nineteenth centuries by numerous urban epidemics in the West Indies, Central and South America, and the eastern part of the USA as far north as New York. Epidemics in more temperate regions of the western hemisphere were the result of introductions through seaports and of transport of mosquito vectors and viruses along commercial shipping routes. The work of the US Army Commission in Cuba established that urban transmission of YFV from human to human was infected by *Ae. aegypti* mosquitoes (Reed 1902), and subsequent eradication measures against this mosquito, and immunization using a live attenuated virus vaccine (see below), effectively controlled urban YF in the Americas and West Indies, respectively. However, the disease persisted sporadically in forest areas of both Africa and South America as a consequence of sylvatic cycles involving monkeys and forest-dwelling mosquitoes, e.g. *Haemagogus* and *Sabethes* spp. in South America, *Ae. africanus* in East Africa, and a variety of *Aedes* spp. in West Africa (Strode 1951). In the past 20 years, *Ae. aegypti* has reinfested nearly all tropical American countries, putting this region at the highest risk of urban epidemics of YF in more than 50 years.

In humans, YF illness varies from an inapparent infection to a fulminating disease terminating in death; three stages (infection, remission, and intoxication) can be commonly recognized. After an incubation period of 3–10 days, there is sudden onset of fever, rigors, headache, and backache. The patient is usually intensely ill and restless with flushed face, swollen lips, bright red tongue, and congested conjunctivae; many patients suffer from nausea and vomiting. A bleeding tendency may be seen early on. This stage of active congestion is followed after 2–3 days by a brief remission and then a resumption of febrile illness. The facial edema and flushing are replaced by a dusky pallor, the gums

become swollen and bleed easily, and there is a pronounced hemorrhagic tendency with black vomit, melena, and ecchymoses. The pulse rate is slow, despite the high fever, and the blood pressure falls, resulting in albuminuria, oliguria, and anuria. Death, when it occurs, is usually within 6–7 days of onset, and is rare after 10 days of illness. The jaundice, which gives the disease its name, is generally apparent only in convalescing patients. In patients with intoxication, mortality may occur in 20–50 percent. In a recent outbreak in Nigeria, mortality was over 50 percent (Nasidi et al. 1989). Most patients with severe disease will have leukopenia, thrombocytopenia, elevated liver enzymes, and coagulation defects. At autopsy the organs most affected are the liver, spleen, kidneys, and heart. Typically, midzonal necrosis is apparent in the liver, affecting cells around the periphery of the lobule and sparing areas around the central vein. Hyaline necrosis is evident and Councilman inclusion bodies are usually present.

Treatment is supportive and confined to nonspecific measures, including maintenance of fluid and electrolyte balances and replacement of any substantial amounts of blood lost through hemorrhage. Laboratory diagnosis can be made by virus isolation, serology, polymerase chain reaction (PCR), and immunohistochemistry. One dose of live-attenuated 17D vaccine provides complete protection for 10 years. A French vaccine prepared from a neurotropic strain of YFV has been widely used in Africa. It confers good protection and is cheaper than the 17D vaccine, but because it has caused adverse reactions, including a number of cases of encephalitis, its use is limited.

Dengue/dengue hemorrhagic fever (DHF)

There are four DENV serotypes: DENV-1, DENV-2, DENV-3, and DENV-4. These viruses are closely related to each other antigenically, and crossreactivity occurs in serological tests. However, there is no lasting cross-protective immunity; cross-protection between DENV serotypes lasts for only a few months. Thus, individuals can have as many as four dengue infections in their life, one with each serotype.

Major DENV epidemics have been caused by all four DENV serotypes. Generally one serotype predominates in an area until increased herd immunity decreases transmission. Then another serotype predominates. DENV changes genetically during natural transmission, and significant biological differences have been shown between strains of the same serotype (Russell and McCown 1972; Gubler and Rosen 1977; Gubler et al. 1978).

The epidemiology of the four DENV serotypes is similar (Gubler 1988, 1998). All have a worldwide distribution in the tropics and are maintained in most tropical urban centers in a mosquito–human–mosquito cycle. In many urban centers, multiple virus serotypes co-circulate (hyperendemicity). The principal mosquito vector is *Ae. aegypti*, an African species that was spread around the world during the seventeenth, eighteenth, and nineteenth centuries with the slave trade and shipping industry. This species became highly adapted to living in intimate association with humans and is a highly efficient epidemic vector in urban settings. Secondary vectors include other *Ae. stegomia* species such as *Ae. albopictus*, *Ae. polynesiensis*, and *Ae. scutellaris* spp. These secondary vector species can transmit outbreaks, but may be more important as maintenance vectors. DENV are also maintained in forest cycles in Asia and Africa. These are thought to be primitive cycles and involve monkeys and canopy-dwelling *Aedes* spp. mosquitoes that rarely come in contact with humans. Current evidence suggests that these forest cycles are not important in contributing to urban epidemics (Rico-Hesse 1990).

Infection with DENV causes a spectrum of clinical illness, ranging from inapparent infection to mild nonspecific viral syndrome to classical DENV fever to severe and fatal hemorrhagic disease. The clinical picture of classical DENV fever has been described in experimentally infected volunteers (Siler et al. 1926; Simmons et al. 1931). Classic DENV fever is seen in adults and older children. After an infective mosquito bite, there is an incubation period of 4–6 days (range 3–14 days), followed by the sudden onset of fever (which is often biphasic), severe headache, chills, and generalized pains in the muscles and joints. A maculopapular rash generally appears on the trunk between the third and fifth day of illness and spreads to the face and extremities. Lymphadenopathy, anorexia, constipation, and altered taste sensation are common. Occasionally, petechiae are seen on the dorsum of the feet, legs, hands, axillae, and palate late in the illness. In young children, the illness is usually mild, but may be severe. The illness generally lasts for 5–7 days, after which recovery is usually complete, although convalescence may be prolonged. There is leukopenia with a relative lymphocytosis, and thrombocytopenia may occur. Liver enzymes may be elevated and hemorrhagic manifestations may occur.

DHF is a severe form of DENV infection characterized by sudden onset of fever, usually of 2–7 days' duration, and nonspecific signs and symptoms. The critical stage of DHF occurs 24 hours before to 24 hours after the temperature falls to or below normal. During this time, hemorrhagic manifestations usually occur, and signs of circulatory failure may appear. The patient may become restless or lethargic, experience acute abdominal pain, and have cold extremities, skin congestion, and oliguria, usually on or after the third day of illness. Clinical laboratory tests at this time will show thrombocytopenia (platelet count $<100\ 000/mm^3$) and evidence of a vascular leak syndrome, which may cause hypovolemia, shock, and death. The most common hemorrhagic manifestations are skin hemorrhages, but epistaxis, bleeding

gums, gastrointestinal hemorrhage, and hematuria may occur.

DHF is most commonly observed in children under the age of 15 years in Asia, but in the Pacific and Americas, DHF also occurs in adults (Gubler et al. 1978; Guzman et al. 1984a, b; Schatzmayr et al. 1986; Dietz et al. 1996). The pathogenesis of DHF is still not well understood. It is hypothesized that classical DHF with a capillary leak syndrome has a unique immunopathologic basis associated with heterologous dengue antibody-dependent enhancement of viral infection of cells of the mononuclear phagocyte lineage (Halstead 1980). Infection of these cells stimulates the release of a vasoactive mediator(s) that apparently causes increased vascular permeability; if not promptly detected and corrected, this can lead to hypovolemia, shock, and death. Although the risk of DHF is higher in children experiencing a second dengue infection, DHF also occurs in patients experiencing primary infections with DENV, suggesting that heterologous DENV antibody (previous infection) is not a necessary prerequisite for DHF. Furthermore, some strains of DENV cannot be enhanced in vitro (Rosen 1977; Gubler et al. 1978). Both field and laboratory evidence has been accumulating in recent years that supports a more prominent role of viral factors in the pathogenesis of DHF and suggesting that virus strain and serotype are also important risk factors for severe disease (Rosen 1986b, 1989; Gubler 1988, 1998; Trent et al. 1989; Rico-Hesse et al. 1997). Another complicating factor is that DEN infections with severe hemorrhage, but no evidence of a capillary leak syndrome, may have another pathogenetic mechanism (Gubler 1988). Because there is not a good animal model for DHF, a full understanding of the pathogenetic mechanism of severe dengue disease will have to await careful field studies in dengue endemic areas.

DENV infection can be diagnosed by virus isolation, serology, PCR, and immunohistochemistry. Although laboratory tests are reliable for diagnosis, they are not rapid and should not be used to make management and treatment decisions in a clinical setting. Instead clinicians should rely on clinical laboratory tests that can be used to monitor whether there is a capillary leak.

Case-fatality rates can be as high as 20–40 percent in DHF/DSS, but can be reduced with early diagnosis and proper case management using fluid replacement therapy. On average, DHF case-fatality rates are almost 5 percent. There is no vaccine for DENV/DHF, although significant progress has been made in developing both live attenuated vaccine candidates and second-generation recombinant candidate vaccines using infectious clone technology in recent years (Kinney and Huang 2001). Currently, disease prevention depends exclusively on mosquito control and avoiding mosquito bites.

Japanese encephalitis

Japanese encephalitis virus (JEV) is widespread throughout Asia, from the maritime provinces of Russia to South India and Sri Lanka (Umenai et al. 1985; Rosen 1986a). JEV is the most important cause of arboviral encephalitis globally with more than 45 000 cases reported annually. In recent years, JEV, which has been limited to Asia, has expanded its geographical distribution with outbreaks in the Pacific (Paul et al. 1993; Hanna et al. 1995). Epidemics occur in late summer in temperate regions, but the virus is enzootic and occurs throughout the year in many tropical areas of Asia. JEV is maintained in a natural enzootic cycle involving culicine mosquitoes and water birds. The virus is transmitted to man by *Culex* mosquitoes, primarily *Cx. tritaeniorhynchus*, and related species, which breed in rice fields. Pigs are the primary amplifying hosts of JEV in the peridomestic environment.

The incubation period of JE is 5–14 days. Onset of symptoms is usually sudden, with fever, headache, and vomiting. The illness resolves in 5–7 days if there is no CNS involvement. In those patients with CNS involvement, lethargy is common, faces are expressionless, and there are sensory and motor disturbances affecting speech, the eyes, and limbs. There may be confusion and delirium progressing to coma, with convulsions in children as a presenting sign. Weakness and paralysis may affect any part of the body. The lesions are generally upper motor neuron in character. Neck rigidity and a positive Kernig sign are found, and reflexes are abnormal. Initial leukocytosis is followed by leukopenia. The mortality in most outbreaks of JE is less than 10 percent, but is higher in children and has exceeded 30 percent in some outbreaks in India and in Korea (Umenai et al. 1985). Neurological sequelae in patients who recover are reported in up to 30 percent of cases.

A formalin-inactivated vaccine prepared in mice infected with the Nakayama strain of JEV is used widely in Japan, Korea, Taiwan, and Thailand; in China, an inactivated vaccine prepared in primary hamster kidney cell cultures has been given to millions of children. A live-attenuated vaccine prepared in primary hamster kidney cell culture has also given very promising results in children in China (Xin et al. 1988).

St. Louis encephalitis

St. Louis encephalitis (SLE) is one of the most important mosquito-borne encephalitides in the USA, causing periodic epidemics in the midwest and southeast. SLEV is prevalent throughout the western hemisphere from Canada to Argentina, but epidemics are unknown in South and Central America (Monath and Tsai 1987). SLEV is maintained in a culicine mosquito–bird–mosquito cycle, with periodic amplification by peridomestic birds

and *Culex* mosquitoes. In Florida, the principal vector is *Cx. nigripalpus*, in the Midwest, *Cx. pipiens pipiens* and *Cx. p. quinquefasciatus* and in the western United States, *Cx. tarsalis*.

Only a small proportion of SLE infections lead to clinical illness. Onset of illness is usually insidious, with a nonspecific prodrome. The disease is generally milder in children than in adults. In those children who do have severe disease, however, there is a high rate of encephalitis. The elderly are at highest risk for severe disease and death. No vaccine is yet available, and prevention, therefore, is by mosquito-control measures.

West Nile virus

West Nile virus (WNV) is closely related to JEV, Murray Valley encephalitis virus (MVEV), and SLEV. It, like the other flaviviruses that cause encephalitis, has a natural maintenance cycle involving wild birds and mosquitoes. Historically, the geographical distribution of WNV included Africa, Central Asia, the Middle East, and Europe. In 1999, WNV was identified in the western hemisphere for the first time in New York City and has since spread throughout most of the USA, southern Canada, and the northern part of Mexico along the US boarder (Gubler et al. 2000; Marfin et al. 2001; Petersen and Roehrig 2001; Campbell et al. 2002; Petersen and Marfin 2002; Roehrig et al. 2002). Genomic sequencing studies have identified two lineages of WNV (Mathiot et al. 1990; Lanciotti et al. 1999, 2002; Scherret et al. 2001). Lineage 1 contains viruses that have caused major human outbreaks in Africa, Europe, the Middle East, and the USA. Also included as a lineage 1 WNV is the Australian flavivirus, KUNV. KUNV normally causes mostly asymptomatic infections, but occasional cases of encephalitis have been reported (Muller et al. 1986). Lineage 2 WNVs are primarily enzootic viruses that circulate in Africa and have not been associated with human epidemics. The lineage 1 North American WNV is most closely related to a genotype in Israel (Jia et al. 1999; Lanciotti et al. 1999), indicating that this was the most likely source of the North American WNV.

An interesting aspect of the North American/Israeli strain of WNV is its virulence for some of its avian reservoirs, especially members of the family *Corvidae* (e.g. crows, blue jays, etc.), humans, horses, and a number of other animal species. High virulence is not common among other strains of WNV and avian virulence in the form of dead bird surveillance has been exploited as a particularly effective method to identify WNV activity in North America (Eidson et al. 2001a, b). To date, more than 150 species of birds and 19 other mammalian species have been shown to be infected with WNV in the USA (Komar et al. 2002). Based on seroprevalance of WNV-reactive antibodies in birds and their large populations, passerine birds appear to be major avian reservoirs for WNV in North America. Thousands of horses have been infected with WNV in the USA since 1999, with a case-fatality rate of about 25 percent. Studies suggest, however, that the horse is a dead-end host for WNV (Bunning et al. 2002). In addition, WNV morbidity and/or mortality have been documented in other mammals. A killed WNV vaccine has been developed for horses. Beginning in 2001, it has been used extensively in the USA. How, or if, this vaccination program has modified current the equine epizootic in North America is not known. A DNA vaccine also shows promise for disease prevention in horses (Davis et al. 2001).

The principal mosquito vectors belong to the genus *Culex*, including *Cx. univittatus* in Africa, *Cx. pipiens* and *Cx. modertus* in the Middle East and Europe, and the *Cx. vishnui* and *Cx. tritaeniorhynchus* complexes in Asia. While *Cx. pipiens pipiens* and *Cx. p. quinquefaciatus* appear to be primary vectors among the bird reservoirs in North America, at least 40 other species of mosquitoes have been shown to be infected with WNV, and several of them are being investigated as possible bridge vectors to humans and horses (Nasci et al. 2001; Turell et al. 2001, 2002; Dohm et al. 2002). In addition, WNV has been isolated from both soft and hard ticks, which may be involved in the maintenance cycle in some areas (Gromashevsky et al. 1973; Lvov et al. 2000).

Human infection is usually mild and generally presents as a nonspecific viral syndrome. In those cases with more severe disease, meningoencephalitis is the most common complication. In the USA, WNV encephalitis can present as a poliomyelitis-like syndrome (Glass et al. 2002; Leis et al. 2002). The incubation period can range from 2 to 15 days post-infection. A single case of hepatitis caused by WNV has been reported from Africa. The case-fatality rate in severe cases is about 10 percent, but like SLE, may be much higher in elderly people above the age of 50. The summer of 2002 in the USA saw the largest human outbreak of WNV meningo-encephalitis ever documented with more than 3 800 human cases. Results of human serosurveys in the USA suggest that 1:150 WNV infections progress to encephalitis in persons less than 65 years, but may be as high as 1:50 in older individuals (Mostashari et al. 2001).

Recent studies have also demonstrated that WNV can be transmitted through transfusion or transplantation of virus-contaminated blood or other tissues, through human breast milk, or transplacentally. While these may be infrequent events, the blood contamination may necessitate screening of blood products for the presence of WNV during intense human viral outbreaks.

There is no human vaccine for WNV. Prevention relies on mosquito control and protection from mosquito bites to reduce the risk of exposure. Definitive diagnosis can only be made using laboratory tests to isolate the virus or detect specific antibodies.

Murray Valley encephalitis

Murray Valley encephalitis (MVE) is a zoonosis that occurs only in Australia and New Guinea. The virus is closely related to JEV, WNV, SLEV, and several other flaviviruses, all of which are zoonoses and cause encephalitis in humans. MVEV, first isolated in 1951, has been and is responsible for major epidemics of encephalitis in Australia. Like other flaviviruses of this group, the virus is believed to be maintained in a natural cycle involving water birds and mosquitoes. However, this is not proven and serological evidence suggests other hosts are commonly infected. The major mosquito vector appears to be *Cx. aunutirostris*, although other species such as *Ae. normanensis* and other *Aedes* spp. may play a role, especially in the maintenance cycle. The inapparent to apparent ratio infection is about 500:1. Clinical disease is characterized by sudden onset of a nonspecific viral syndrome with fever, headache, nausea/vomiting, anorexia, and myalgias, followed by drowsiness, malaise, irritability, mental confusion, and meningismus. There is a pleocytosis and leukocytosis. In severe cases, there may be hyperactive reflexes, spastic paresis, convulsions, coma, and death. The case-fatality rate is about 20 percent; neurological sequaleae occur in a significant number of those patients that survive. All age groups are affected.

Viremia in humans has not been documented in MVEV infections, and it is likely that they are dead-end hosts. The pathological changes that occur in the central nervous system are similar to those caused by other viral zoonoses that cause encephalitis. Definitive diagnosis must rely on laboratory tests that detect specific antibody to MVEV.

There is no vaccine for MVE. Prevention relies on mosquito control and individuals taking responsibility to protect themselves against mosquito bites.

Other mosquito-borne infections

ILHÉUS VIRUS

Ilhéus virus (ILHV) is active over wide areas of Central and South America, including Trinidad, and is probably maintained in a forest cycle involving birds and mosquitoes. Most human infections are asymptomatic, but occasional cases of encephalitis are recognized.

ROCIO VIRUS

Rocio virus (ROCV) is antigenically related to SLEV and is known only from Brazil. Clinically it causes CNS disease similar to other flaviviruses that cause encephalitis. It has caused major epidemics in Brazil, principally in males 15–30 years of age (de Souza Lopes et al. 1981; Iversson 1988).

SPONDWENI VIRUS

Spondweni virus (SPOV) is present in South Africa, and has produced overt human disease in a few expatriates in West Africa (Wolfe et al. 1982).

USUTU VIRUS

The historical range of Usutu virus (USUV) is in East, West and Central Africa. Recently, however, USUV has been isolated from birds in Austria (Weissenbock et al. 2002). A single case with fever and a rash has been reported.

WESSELSBRON VIRUS

Wesselsbron virus (WESSV) has wide distribution in Africa and causes epizootics in sheep, producing abortion and death in newborn lambs and ewes, and less severe disease in goats and cattle (Coetzer and Theodoridis 1982). The virus also infects man in nature and in the laboratory (Justines and Shope 1969).

TICK-BORNE INFECTIONS

Tick-borne encephalitis

Tick-borne encephalitis (TBE) is caused by two closely related viruses that are distinct biologically. The eastern subtype causes Russian spring–summer encephalitis (RSSE) and is transmitted by *Ixodes persulcatus*. The western subtype is transmitted by *Ixodes ricinus* and causes Central European encephalitis (CEE). The latter name is somewhat misleading, since the condition occurs in foci extending from Scandinavia in the north to Yugoslavia and Greece in the south.

Of the two subtypes, RSSE is the more severe infection, having a case-fatality rate of up to 25 percent in some outbreaks, whereas mortality in CEE seldom exceeds 5 percent. Both viruses are maintained in natural cycles involving a variety of mammals and ticks; the latter serve as the main reservoir host by passing the viruses from generation to generation by transovarial and trans-stadial transmission. Human exposure occurs in the spring and summer months in temperate zones and in fall and winter in the Mediterranean, when the ticks are more active. Most human exposure is associated with work or recreational activities in enzootic areas. The incubation period is 7–14 days. Infection usually presents as a mild, influenza-type illness or as benign, aseptic meningitis, but may result in fatal meningoencephalitis. Fever is often biphasic, and there may be severe headache and neck rigidity, with transient pareses of the limbs, shoulder girdle, or, less commonly, of the respiratory musculature. A few patients are left with residual flaccid paralysis (Ackermann et al. 1986). Although the great majority of TBE infections follow

exposure to ticks, infection has occurred through the ingestion of infected cows' or goats' milk.

Inactivated vaccines are available against both eastern and western subtypes of TBE. The vaccine against the western subtype is highly effective (Kunz et al. 1980). Definitive diagnosis can only be achieved by specific laboratory tests to detect antibody.

Louping ill

Louping ill (LI) is derived from an old Norse word meaning 'to leap.' Louping ill virus (LIV) is a member of the TBEV complex. It is known in the British Isles as a disease of sheep characterized by CNS manifestations, in particular, cerebellar ataxia, paralysis, and death. It has never been a serious hazard to humans: most reported cases are the result of laboratory infections. A few natural infections do occur in persons closely associated with sheep. The illness is generally biphasic with encephalitic involvement in the second stage. The vector is *I. ricinus* and the virus is maintained in rodents, deer, and ground-living birds (Reid 1988).

Powassan virus

Powassan virus (POWV) is a member of the TBEV complex. It is thought to be a rare cause of acute viral CNS disease in Canada and the USA, but is also present in the former Soviet Union, where it has been recovered from mosquitoes, ticks, and humans. It was first isolated from the brain of a 5-year-old child who died in Ontario in 1958, and has since caused a number of cases of encephalitis in Canada and the eastern USA (Artsob 1988). However, with intensified surveillance for neurological disease caused by WNV in the northeastern USA, four cases of POWV encephalitis have been documented (Centers for Disease Control and Prevention 2001). Patients who recover may have residual neurological sequelae. In addition to isolations from humans, the virus has been recovered from ticks (*I. marxi, I. cookei*, and *Dermacentor andersoni*) and from the tissues of a skunk (*Spiligale putorius*) (Johnson 1987). There is clinical and serological evidence that POWV can cause fatal encephalitis in horses, which may be confused with rabies encephalitis (Little et al. 1985).

Kyasanur Forest disease

Kyasanur Forest disease virus (KFDV) was first recognized in 1957 during a fatal epizootic affecting wild monkeys in Mysore (Karnataka) State, India. Since then, thousands of infections have occurred in forest workers with a mortality of up to 10 percent. Until recently it was found only in southwestern India. The virus has been isolated from monkeys, humans, and ticks. The principal tick vector appears to be *Haemaphysalis spinigera*; the vertebrate reservoir host is uncertain (Banerjee 1988). Human infection with KFDV causes a spectrum of illness ranging from inapparent infection to severe hemorrhagic disease. Hemorrhagic manifestations are common and may involve the skin, gums, and gastrointestinal tract. Although CNS involvement is uncommon, there may be signs of meningeal irritation and stiff neck. An inactivated vaccine is available in Europe.

An apparent subtype of KFDV has been isolated from fatal human cases of hemorrhagic disease in Jeddah, Saudi Arabia, associated with meat handlers (Zaki 1997; Besaud 2005). The virus was subsequently isolated from other patients with illness ranging from fatal hemorrhagic disease to viral syndrome. All known human infections to date have been associated with handling meat or drinking unpasteurized camels' milk. The virus appears to be associated with sheep and camels, and to be transmitted by ticks, but no data are available on either the natural vertebrate host or the arthropod vector.

Omsk hemorrhagic fever

Omsk hemorrhagic fever virus (OHFV) is also caused by a tickborne Flavivirus. It was first isolated in association with human disease in Siberia in 1945; illness was characterized by biphasic fever with lymphadenopathy and hemorrhages from mucous membranes. OHFV is antigenically distinct from the eastern and western subtypes of TBEV. Infection may be acquired from ticks, usually *Dermacentor pictus* or *D. marginatus*, or from exposure to infected water voles or muskrats (Lvov 1988).

Other tick-borne infections

MEABAN VIRUS, SAUMAREZ REEF VIRUS, AND TYULENIY VIRUS

These viruses are associated with seabird ticks in France, Australia, and subarctic regions of the USA and the former Soviet Union (Clifford et al. 1971; Lvov et al. 1971; St George et al. 1977; Chastel et al. 1985).

NEGISHI VIRUS

Negishi virus (NEGV) has caused at least two fatal cases of encephalitis in Japan (Okuno et al. 1961). Although tick transmission has not been proven, this virus is closely related to other tick-borne flaviviruses (De Madrid and Porterfield 1974; Furuta et al. 1984; Calisher et al. 1989).

PESTIVIRUS INFECTIONS

Bovine viral diarrhea

Infection with BVDV occurs worldwide in many wild and domestic bovine species. Two clinical syndromes are

recognized in cattle, namely bovine viral diarrhea and mucosal disease. The former is a mild, transient infection with high morbidity but low mortality, which is followed by immunity. Viral infection during pregnancy can result in abortion or the birth of persistently infected offspring, some of which may have teratogenic defects. Two biotypes of virus have been recognized, only one of which is cytopathic. When persistently infected, antibody negative animals carrying the noncytopathic strain virus are reinfected with a serologically related cytopathic strain, they develop mucosal disease, which carries a high mortality (Baker 1987; Brownlie et al. 1987).

Antibodies reactive with pestivirus antigens have been detected in the serum of two children with microcephaly (Potts et al. 1987). With a mAb prepared against BVDV Yolken et al. (1989) detected pestivirus antigens in the feces of infants with gastroenteritis.

Border disease

BDV of sheep, originally recognized in the Scottish border country, occurs also in New Zealand. The causative virus is closely related to that of bovine viral diarrhea (Horzinek 1981; Nettleton 1987).

Classical swine fever (hog cholera)

This important disease of pigs occurs worldwide and is associated with persistent infections, abortion, and congenital malformations (Liess 1987).

CLASSIFICATION

Two decades ago the *Togaviridae* family included a wide variety of small, enveloped viruses with single-stranded RNA genomes of positive polarity of about 4×10^6 Da. These RNAs could serve directly as messenger RNA and were packaged into nucleocapsids demonstrating cubic symmetry. The family name was derived from the Latin *toga* (a Roman mantle or cloak) and refers to the lipid envelope. However, since the *Togaviridae* was first defined, its contents have changed significantly based on accumulated data about viral replication and nucleotide sequences of the genomes. Flaviviruses, pestiviruses, and arteriviruses, which were temporarily brought together with alphaviruses and rubella virus, were finally classified into different families (Weaver et al. 2000). Currently the Togaviridae is comprised of two genera, *Alphavirus* and *Rubivirus*. Twenty-eight known alphaviruses are grouped into eight complexes, the prototypes of which are *Western equine encephalitis virus* (WEEV), *Eastern equine encephalitis virus* (EEEV), *Venezuelan equine encephalitis virus* (VEEV), *Semliki Forest virus* (SFV), *Middelburg virus* (MIDV), *Ndumu virus* (NDUV), *Trocara virus* (TROCV), and *Salmon pancreas disease virus* (SPDV) (Table 1). Partially or completely sequenced genomes of different alphaviruses reveal at least 60 percent nucleotide sequence identity in the nonstructural and 40 percent or more identity in the structural proteins. Sequencing and phylogenetic studies have indicated that WEEV, *Highlands J virus* (HJV) and *Fort Morgan virus* (FMV) are recombinant New World alphaviruses whose glycoproteins were derived from a Sindbis-like ancestor, the remainder of the genome being derived from an EEE-like ancestor (Figure 1, p. 3). Phylogenetic studies suggest only three clearly defined virus groups: a VEE/EEE group, an SF group (including MIDV), and a Sindbis group (Powers et al. 2001).

Most alphaviruses are described as arthropod-borne, or arboviruses that are maintained in nature through biological transmission among vertebrate hosts by arthropod vectors, predominantly mosquitoes (Griffin 2001a). However, the recent finding of salmon pancreas disease and sleeping disease alphaviruses indicates that arthropod vectors may not be required for the circulation of all alphaviruses.

Alphaviruses have highly differing abilities to cause disease in humans and animals. Some of them, including VEEV, EEEV and WEEV, can cause severe epidemic encephalitis, with a high mortality rate. Infection by others usually leads to either serious, but not life-threatening, illnesses or clinically inapparent infection with mild symptoms, including headache, fever, skin rashes, and arthritis. Many alphaviruses (at least mosquito-transmitted ones) are believed to have similar lifecycles, structures of viral particles, and replication strategies (Griffin 2001a).

The genus *Rubivirus* (Rubella) consists of a single known member, *Rubella virus*. Alphaviruses and rubella virus do not have significant primary sequence

Table 1 *List of alphaviruses*

Antigenic complex	Species (abbreviation)	Subtype	Clinical syndrome	Distribution
Barmah Forest	*Barmah Forest virus* (BFV)		Febrile illness, rash, arthritis	Australia
Eastern equine encephalitis (EEE)	EEE virus (EEEV)		Febrile illness, encephalitis (none recognized in Latin America)	North, Central, South America
Middelburg	*Middelburg virus* (MIDV)		None recognized	Africa
Ndumu	*Ndumu virus* (NDUV)		None recognized	Africa
Semliki Forest	*Semliki Forest virus* (SFV)		Febrile illness	Africa
	Chikungunya virus (CHIKV)		Febrile illness, rash, arthritis	Africa
	O'nyong-nyong virus (ONNV)		Febrile illness, rash, arthritis	Africa
	Getah virus (GETV)		None recognized	Asia
	Bebaru virus (BEBV)		None recognized	Malaysia
	Ross River virus (RRV)	Sagiyama	Febrile illness, rash, arthritis	Australia, Oceania
	Mayaro virus (MAYV)		Febrile illness, rash, arthritis	South and Central America, Trinidad
	Una virus (UNAV)		None recognized	South America
Venezuelan equine	VEE virus (VEEV)	IAB	Febrile illness, encephalitis	North, Central, South America
encephalitis (VEE)		IC	Febrile illness, encephalitis	South America
		ID	Febrile illness, encephalitis	South America, Panama
		IE	Febrile illness, encephalitis	Central America, Mexico
	Everglades virus (EVEV)		Febrile illness, encephalitis	Florida (USA)
	Mucambo virus (MUCV)		Febrile illness, myalgia	South America, Trinidad
		strain 71D1252	Unknown	Peru
	Tonate virus (TONV)		Febrile illness, encephalitis	Brazil, Colorado (USA)
	Pixuna virus (PIXV)		Febrile illness, myalgia	Brazil
	Cabassou virus (CABV)		None recognized	French Guiana
	AG80-663 virus (AGV)		Febrile illness, myalgia	Argentina
	Mosso das Pedras virus (MDPV)		None recognized	Brazil
Western equine encephalitis (WEE)	*Sindbis virus* (SINV)		Febrile illness, rash, arthritis	Africa, Europe, Asia, Australia
		Babanki	Febrile illness, rash, arthritis	Africa
		Ockelbo	Febrile illness, rash, arthritis	Europe
		Kyzylagach	None recognized	Azerbaijan, China
	Whataroa virus (WHAV)		None recognized	New Zealand
	Aura virus (AURAV)		None recognized	South America
	WEEV	Several	Febrile illness, encephalitis	Western North, South America
	Highlands J virus (HJV)			Eastern North America
	Fort Morgan virus (FMV)	Buggy Creek	None recognized	Western North America
Trocara	*Trocara virus* (TROV)		None recognized	South America
Salmon pancreas disease (SPD)	SPD virus (SPDV)		Pancreatic disease (salmon)	Atlantic Ocean and tributaries
		Sleeping disease virus	Sleeping disease (trout)	Worldwide

homology in structural and nonstructural proteins. However, the coding strategies, their genomes, mechanisms of replication and structure of viral particles demonstrate a number of similarities, suggesting a common ancestry and supporting their inclusion in the same family *Togaviridae*.

VIRION STRUCTURE

Alphavirus virions are about 70 nm in diameter and are composed of an icosahedral nucleocapsid with T = 4 symmetry, surrounded by a lipid envelope containing glycoprotein spikes. The three-dimensional organization of viral particles has been determined for Ross River virus (RRV), Sindbis virus (SINV), and VEEV, which represent three different *Alphavirus* complexes. Electron cryomicroscopy and image reconstruction demonstrated that for these viruses the envelope glycoproteins are arranged on the outer surface of particles in a very similar way. The 240 heterodimers of E1 and E2 are combined into 80 trimers forming glycoprotein spikes that are distributed on the surface of viral particles in a T = 4 icosahedral lattice that mirrors the symmetry of the nucleocapsid. The regularity of spike distribution is determined by the direct interaction of glycoprotein heterodimers with capsid protein subunits. The E1 glycoprotein, which is structurally homologous to the envelope glycoprotein of flaviviruses, appears to lie parallel to the lipid envelope (Lescar et al. 2001), whereas the E2 glycoprotein projects outward from the virion to form the spikes.

GENOME STRUCTURE AND REPLICATION

The *Alphavirus* genome is a single-stranded RNA molecule of positive polarity nearly 12 000 nucleotides in length, with a sedimentation coefficient of ca. 42–49S (Schlesinger and Schlesinger 2001; Strauss and Strauss 1994). The genomic RNA mimics the structure of cellular messenger RNA: it contains a 5′ methylguanylate cap structure and a 3′ polyadenylate sequence. The nonstructural viral proteins coded by the 5′ two-thirds of the genome are translated directly from this RNA immediately following its introduction to the cytosol. Structural proteins are coded by the subgenomic RNA that corresponds to the 3′ one-third of the genome. The subgenomic 26S RNA, transcribed from the subgenomic promoter located on the minus-strand intermediate of

the viral genome, is also capped and polyadenylated. The full-length minus-strand intermediate is synthesized on the template of viral genomic RNA and serves as a template for both subgenomic and genomic RNAs. The general scheme of *Alphavirus* replication is demonstrated in Figure 2. Synthesis of all three RNAs is asymmetric and highly regulated. Minus-strand synthesis is detectable only within the first 4 h post infection, whereas later only plus-strand RNAs (genome and subgenome) are being synthesized. This regulation is achieved via the sequential processing of the nonstructural proteins. Initially they are synthesized for different alphaviruses as two polypeptides, P123 and P1234, or just single P1234. This difference in synthesis of nonstructural proteins depends on the presence of the opal codon at the end of nsP3. Some alphaviruses contain this terminating codon, and P1234 can be synthesized only upon readthrough of the UGA that occurs with 5–20 percent efficiency. Other alphaviruses contain arginine or cysteine codons in place of UGA, and only P1234 is translated. This polyprotein comprises sequences of all four nonstructural proteins, nsP1, nsP2, nsP3, and nsP4, and its processing is mediated by the protease domain of nsP2. First autoproteolytic cleavage is performed in *cis* and results in the release of P123 and nsP4. These two proteins form the viral component of the replicative complex, and this replicative complex is active for minus-strand synthesis but is inefficient in generating the plus-strand genome and subgenomic RNAs. Further cleavage of nsP1/nsP2 and nsP2/nsP3 junctions is also performed by nsP2 protease, this time in *trans*, which changes the template specificity of replicative complex by making it incapable of minus-strand RNA synthesis and significantly increasing its activity in plus-strand RNAs production. The time of genomic and subgenomic RNA synthesis concurs with the most efficient release of viral particles, which requires high-level production of viral genomes and structural proteins for packaging. In spite of a great deal of progress in understanding *Alphavirus* genome replication, the detailed mechanism of viral nonstructural protein functioning is not completely understood. nsP1 possesses both guanine-7-methyltransferase and guanyltransferase activities required for capping of both genomic and subgenomic RNA. This protein also appears to be involved in binding of the replicative complexes to the membranes. nsP2 has a number of activities. Its amino terminal domain is considered to have helicase function,

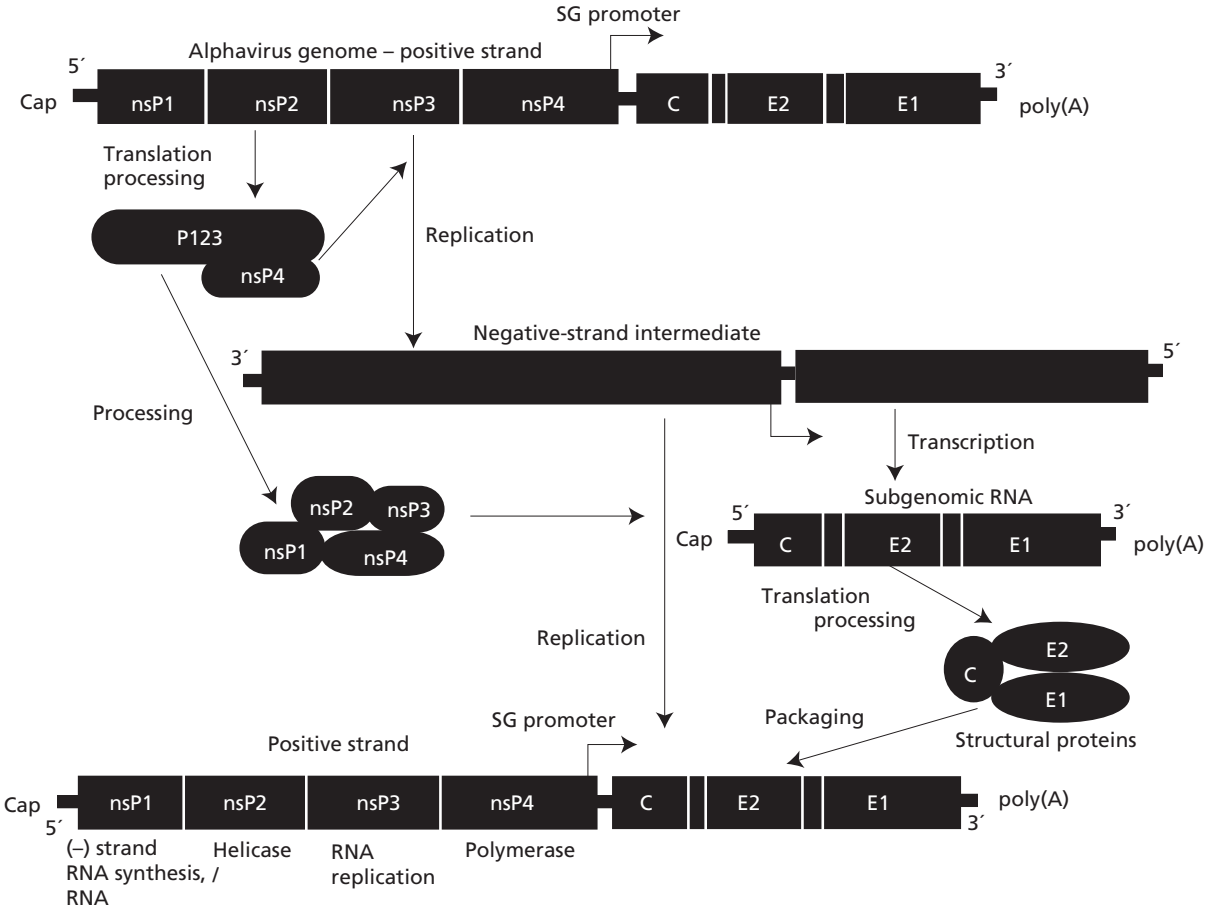

Figure 2 *Organization of the* Alphavirus *genome and schematic presentation of* Alphavirus *replication*

and the carboxy terminal part of the protein is a protease that orchestrates the processing of nonstructural proteins. Point mutations in this protein or in the nsP2/nsP3 cleavage site change the ratio of genome/subgenome RNA synthesis, suggesting that this protein is involved in the functioning of the subgenomic promoter. This protein accumulates in infected cells in a ten-fold excess to nsP4, and a significant fraction is transported to the nucleus. A number of mutations in this protein convert cytopathic alphaviruses, SINV and SFV into noncytopathic variants, which can persist in some cell lines of vertebrate origin (Frolova et al. 2002). These facts suggest that, in addition to its role in RNA replication, nsP2 may have additional functions in virus–host cell interactions. nsP3 is the least-studied protein, with unidentified functions. It can tolerate extensive deletions in C-terminal sequence that have very low sequence identity among alphaviruses, but mutations in the other fragments can make virus replication temperature sensitive. nsP4 is the RNA polymerase and contains the characteristic GDD motif found in all RNA-dependent polymerases. Mutations in this protein can make replicative complexes incapable of both minus- and plus-strand RNAs synthesis.

Alphavirus genomes contain a number of conserved sequences, so-called *cis*-acting elements that are required for replication. These short sequences include a 19-nt conserved sequence element (CSE), which immediately precedes the 3′ terminal poly(A) tract. The location of the 19-nt CSE suggests that it is an important element of the promoter for minus-strand RNA synthesis. Mutations in this sequence are either lethal or significantly alter virus replication. Another conserved sequence, 24-nt CSE, was identified as a promoter for transcription of the subgenomic RNA that functions on the minus-strand replicative intermediate. The 5′ termini of viral genomes appear to contain at least two functional elements. The 51-nt CSE (nt 155–205 of SINV) is located inside the nsP1-coding sequence and is predicted to form two short stem-loop structures. This CSE was shown to function as a replicational enhancer that operates in a host-dependent manner. Point mutations in this element alter virus replication in more mosquito cells than in cells of mammalian origin. The 5′UTR of alphaviruses was always believed to contain a promoter element that is required for initiation of the plus-strand RNA synthesis, and mutations in the 5′UTR significantly downregulate virus replication. The 5′ *cis*-acting elements not only determine plus-strand RNA synthesis when present on the 3′ end of minus-strand replicative intermediate, but control the minus-strand synthesis as well. The compelling evidence suggests that the 5′ and 3′ ends of *Alphavirus* genome RNAs interact to initiate replication, and this interaction is probably achieved by bringing them into close proximity via translation initiation factors.

STRUCTURAL PROTEINS

Alphavirus structural proteins are translated from the subgenomic RNA. Like the nonstructural proteins, they are synthesized as a single polypeptide that is cleaved both co- and post-translationally. Structural proteins are coded in the order capsid (C), E3, E2, 6K, and E1. The capsid is 260–270 amino acids in length (30–34 kDa), and the crystal structure has been solved for Sindbis virus. The capsid protein is synthesized first, possesses a serine protease activity, but in contrast to the nonstructural protease, the nsP2, it acts only in *cis* and cleaves itself from the polypeptide chain that is still being translated. This cleavage releases the signal peptide from the E3 (10 kDa) protein, leading to translocation of both E3 and E2 (PE2, sometimes called P62) into the endoplasmic reticulum (ER). PE2 remains attached to membranes via hydrophobic amino acids in the carboxy terminal part that function as a membrane anchor. The very end of the PE2 contains a signal sequence for translocation into the ER of the amino terminal part of the next short protein, 6K, whose role in virus particle formation is not well understood. In turn, the C-terminal part of 6K serves as the signal peptide required for transport of the last protein, E1, into ER. The latter protein also possesses a hydrophobic anchor on the C terminus. Proteolytic cleavages between PE2 and 6K, as well as between 6K and E1, are performed by cell signalases. The last, very critical, cleavage in the E3/E2 cleavage site is accomplished by a furin-type protease and is required for viral infectivity. During transport to the plasma membrane in secretory vesicles, the envelope proteins are postranslationally modified: E2 (420–424 amino acids) and E1 (438–442 amino acids) acquire oligosaccharides, become palmitoylated, and form heterodimers.

Formation of *Alphavirus* particles is based on specific RNA–protein and protein–protein interactions. The nucleocapsid protein is capable of selectively packaging viral genomes. It recognizes the encapsidation signal(s) located in the sequence of the nonstructural proteins in the viral genomic RNA and, after further oligomerization, 240 molecules of the capsid protein form an icosahedral nucleocapsid. During the final steps of viral replication, the capsid protein molecules in completely or partially assembled nucleocapsids interact with the cytoplasmic domain of E2 in E1–E2 heterodimers on the cell membrane. This leads to envelopment of the nucleocapsid by the plasma membrane containing glycoprotein spikes, and to the release of virus particles. This stage of virus maturation is not well understood, but it has been demonstrated that nucleocapsids undergo conformational changes and heterodimers of glycoproteins appear to assemble into trimeric spikes.

Because of their close association, E1 and E2 share a number of biological functions and antigenic properties.

The glycoprotein spike functions both in attachment to cellular receptors and in fusion with cellular membranes. The E2 glycoprotein elicits high-titer virus-specific neutralizing antibody. Two domains capable of eliciting neutralizing antibody have been identified in the E2 glycoprotein: amino acids 114–120, 180–220 (or 230–250 for RRV) using monoclonal antibody neutralization escape variants and rapid penetration variants. Antibodies to the carboxyl-proximal domain neutralize virus infectivity by blocking virion attachment to susceptible cells. Antibodies to the E2 glycoprotein can also block virus hemagglutination, presumably because of its close association with E1. The amino terminal 25 amino acids of the VEEV E2 glycoprotein protect mice from virus challenge. Mutations in the E2 glycoprotein have been associated with differences in virulence and the ability to infect and replicate in mosquitoes.

The E1 glycoprotein contains a highly conserved amino acid sequence (amino acids 80–96), which has sequence and chemical similarities to regions responsible for cell membrane fusion in orthomyxoviruses and paramyxoviruses. Mutation of this region alters the fusion characteristics of the virus. Because cell-membrane fusion seems, therefore, to be mediated by the E1 glycoprotein, it is not surprising that this glycoprotein elicits potent hemagglutination-inhibiting antibody. Virus-neutralizing anti-E1 antibodies have also been identified. Binding of these antibodies has been associated with E1 amino acid 132 using monoclonal antibody neutralization escape variants. Anti-E1 antibodies are usually not serotype specific and fix complement well.

Many of the biologically important epitopes on both the E1 and the E2 glycoproteins are conformational. This result makes mimicking these antigens in subunit or peptide vaccines difficult. The C protein elicits broadly cross-reactive antibody and is also a major complement-fixing antigen.

VIRUS–HOST CELL INTERACTIONS

Most data on *Alphavirus* replication in vitro were derived from experiments on relatively nonpathogenic members of the genus, SINV and SFV, but are probably applicable to most members of the genus. In general, alphaviruses can infect a wide variety of hosts and cell lines of vertebrate and invertebrate origin. Infection is initiated by virion attachment to cellular receptors. Their broad host range strongly indicates that alphaviruses can either attach to multiple receptors on the cell surface or use a very conserved protein as a receptor. Both of these assumptions appear to be correct. Several receptors have been identified for SINV in different cells (reviewed by Strauss and Strauss 1994). At the same time, it was unambiguously demonstrated that after adaptation of SINV or VEEV to BHK-21 cells that are traditionally used for their propagation, both viruses accumulate point mutations in structural glycoprotein E2, causing them to bind efficiently to heparan sulfate-like molecules (Griffin 2001a). The E2 is a protein that interacts directly with cell receptors. It is generally believed that amino acids 180–220 are directly involved in this interaction, because a considerable fraction of antibodies with neutralizing activity are specific to this peptide. Alphaviruses enter the cells via the endocytic pathway. Next, internalized virus-containing vesicles transform into endosomes, and an acidic pH leads to conformational changes in the glycoprotein spikes, trimerization of the E1 subunits, and fusion of viral and endosomal membranes. The E1 glycoprotein contains a very conserved peptide (amino acids 80–96) that was suggested to have fusogenic activity. It was recently demonstrated that the three-dimensional structure of E protein of tick-borne encephalitis virus (*Flavivirus* genus) and E1 of SFV have a number of similarities, particularly in the position of their fusogenic domains (Lescar et al. 2001). Fusion of the membranes leads to the release of nucleocapsids into the cytoplasm, and the next steps of virus disassembly are performed by ribosomes. *Alphavirus* capsid proteins have a very high affinity to ribosomes, and translocation of capsids to ribosomes results in uncoating of viral genomes and initiation of replication.

Replication of alphaviruses profoundly affects the metabolism of vertebrate cells with the inhibition of protein, RNA, and DNA synthesis playing the central role. Replication appears to activate two competing processes. First, viruses change the cellular environment to meet the needs of their propagation. At the same time, cells respond to virus replication by down-regulating virus growth and activating signaling pathways, followed by secretion of cytokines that prevent dissemination of the infection. The balance between these two mechanisms appears to determine the outcome of infection on the cellular level. In spite of very extensive investigation, it is still undetermined as to what mechanism or combination of different mechanisms defines the five- to ten-fold inhibition of translation that takes place 4–8 h post-infection. However, the translational shutoff is specific to cellular mRNAs. Alphavirus subgenomic RNA is translated very efficiently in this significantly changed intracellular environment owing to the unique structural element, a translational enhancer, located downstream from the initiating AUG. This enhancer and high concentration of the subgenomic RNA make this template the only RNA translated in the cells during the late stage of the infection.

Downregulation of transcription is the second major event in alphavirus-infected cells (Frolova et al. 2002). Both messenger and ribosomal RNAs are synthesized less efficiently, if at all, in permissive cell lines. Transcriptional shutoff may play an important role in the inhibition of interferon (IFN) production by infected

cells and a more efficient dissemination of the infection. Owing to dramatic changes in the intracellular environment, cells die within 24–48 h of infection, and their death is usually accompanied by apoptotic changes (Griffin 2001a).

TRANSMISSION CYCLES AND DISTRIBUTION

Most alphaviruses are **ar**thropod-**bo**rne, or **arbo**viruses, and are maintained in nature through biological transmission between susceptible vertebrate hosts by hematophagous arthropods. Arboviruses multiply and produce viremia in the vertebrate, replicate in the tissues of arthropods – obligately in the midgut and salivary glands – and are transmitted to new vertebrates when the arthropod takes a subsequent blood meal after a period of extrinsic incubation. The term arbovirus has no taxonomic significance and encompasses a heterogeneous group of viruses in seven taxonomic families, including the *Togaviridae* (alphaviruses only).

All alphaviruses are zoonotic and have at least two hosts, one a vertebrate and the other a hematophagous arthropod. The majority of alphaviruses are maintained in complex lifecycles involving one or more nonhuman vertebrate reservoir hosts and one or more arthropod vectors; an example is EEEV (Figure 3). These cycles remain undetected until humans or domesticated animals encroach on an enzootic focus, or the virus escapes the primary cycle via a secondary vector or vertebrate host as the result of some ecological or genetic change. Humans and domestic animals generally become involved only after the virus is brought into the peridomestic environment by a bridge vector, or after they enter an enzootic transmission focus. Humans and domestic animals, which frequently develop clinical illness, are usually considered 'dead-end' hosts because they do not produce viremia sufficient to infect vector arthropods and contribute to the transmission cycle, or because they are not bitten by a sufficient number of vectors when viremic. Many alphaviruses have several different vertebrate hosts and some are capable of

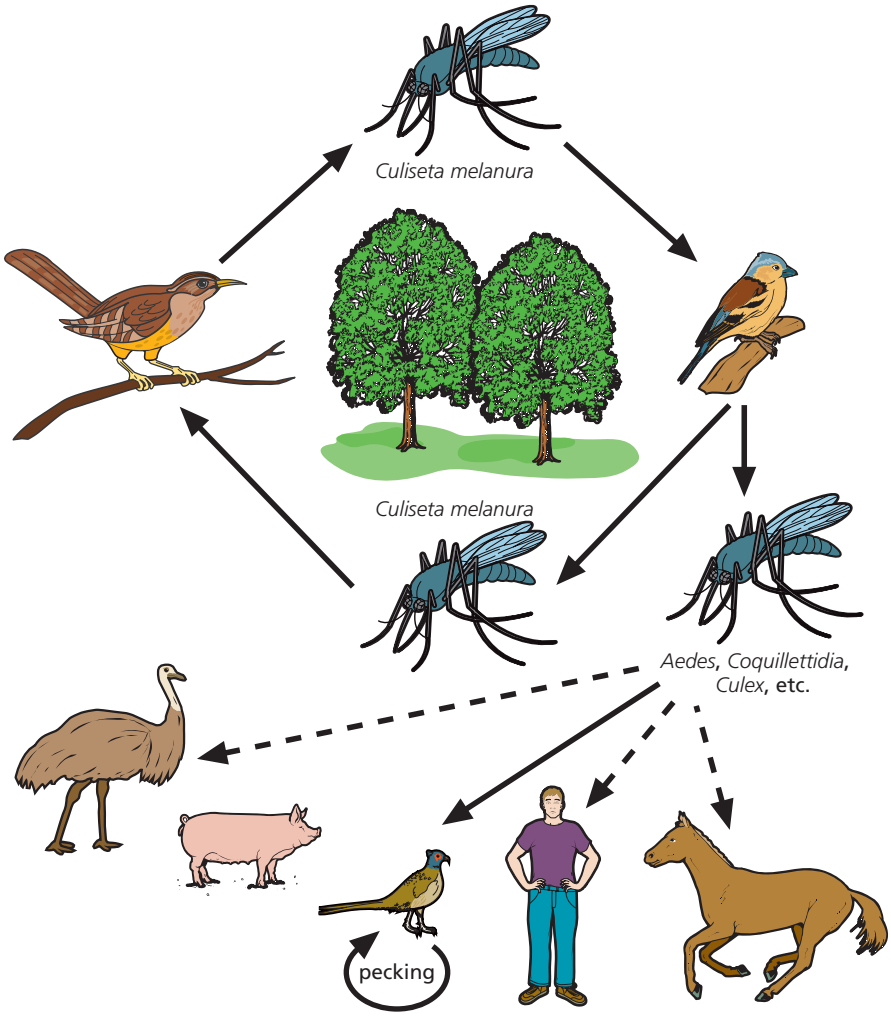

Figure 3 *Transmission cycle of Eastern equine encephalitis virus. Dashed arrows indicate dead-end transmission to hosts that generally do not infect additional vectors or vertebrates.*

transmission by more than one vector. A few alphaviruses, such as Chikungunya virus (CHIKV) and potentially VEEV, cause sufficient viremia in humans to be transmitted in a human–arthropod–human cycle. Transovarial transmission in nature has been demonstrated for SINV and RRV, and may facilitate maintenance of these alphaviruses in nature.

Every *Alphavirus* has its own distinct ecology. For some, such as SINV, EEEV (Figure 3) and WEEV (Figure 4), birds are the principal reservoir host, and others such as VEEV rely principally on rodents. The reservoir hosts of many alphaviruses are not known with certainty. Several, including CHIKV, EEEV, WEEV, VEEV, and SINV, have been isolated from bats, and these hosts deserve further study. All alphaviruses infecting humans are mosquito-borne. Several alphaviruses, including MIDV, CHIKV, and SINV, have also been isolated from ticks, but the significance of these findings is unknown. FMV and Bijou Bridge (a variant of Tonate virus in the VEE complex) are believed to use as their vectors cimicid bugs that occupy bird nests.

Alphaviruses have a nearly worldwide geographical distribution. Previously only the Antarctic area was believed to be *Alphavirus*-free, but a recent discovery of southern elephant seal *Alphavirus* (La Linn et al. 2001) indicates that our knowledge of their distribution is probably far from complete. The majority of alphaviruses are found in tropical developing countries. The greatest number have been described from Africa and South America, where the flora and fauna are diverse and extensive ecological and epidemiological studies have been conducted. The smaller number of viruses described from Asia, which has ecological diversity comparable to that of Africa and tropical America, may simply reflect the lack of surveillance in that region. The geographical distribution of each *Alphavirus* is limited by the ecological parameters governing its transmission cycle, including temperature, rainfall patterns,

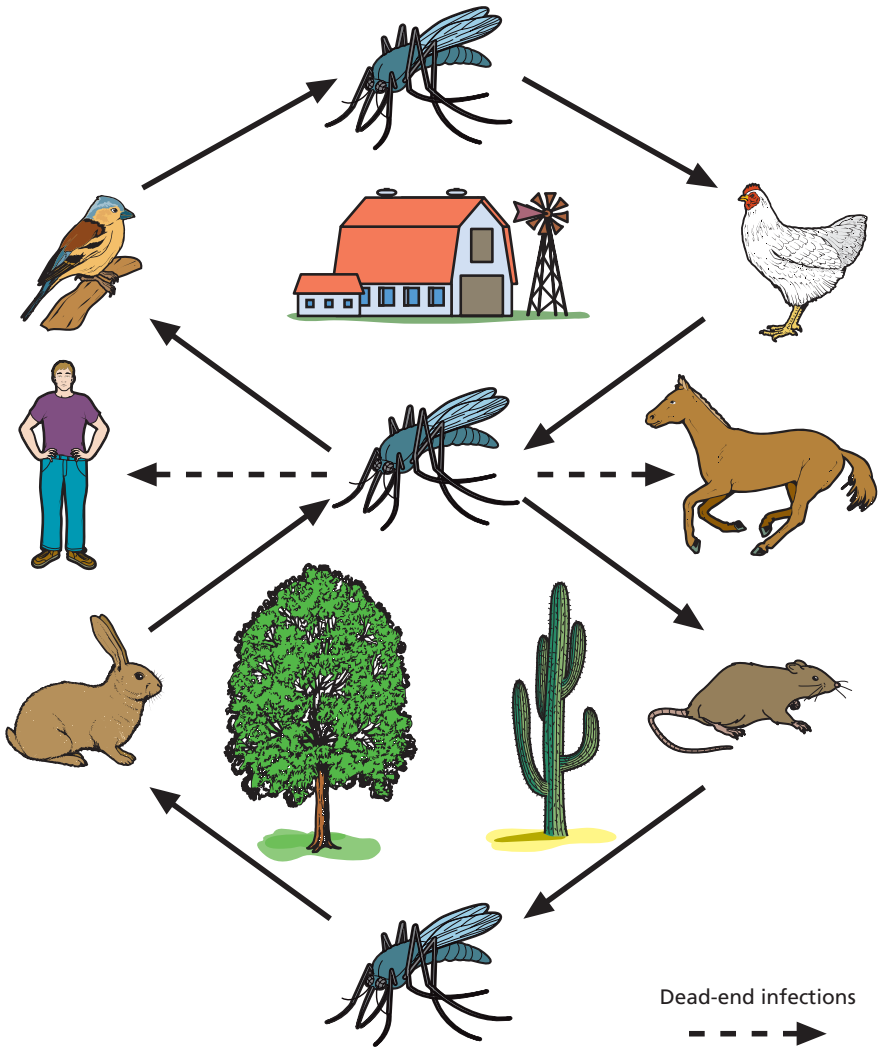

Figure 4 *Transmission cycles of Western equine encephalitis virus*

distribution of the arthropod vector(s), and vertebrate reservoir host(s).

Mosquitoes are by far the most important *Alphavirus* vectors, and bugs (*Cimicidae*) are also involved in the transmission of some alphaviruses. In addition to arthropod transmission, several alphaviruses, such as VEEV, are highly infectious by aerosol and numerous laboratory infections have occurred. Because of their aerosol infectivity, stability, and high degree of virulence, VEEV, EEEV, and WEEV are considered potential agents of biological warfare and terrorism.

DISEASES CAUSED BY ALPHAVIRUSES

Of the 28 currently described alphavirus species, at least 13 are known to cause disease in humans (Table 1). The majority of *Alphavirus* infections in humans cause a nonspecific febrile illness that is easily mistaken for infection by a respiratory virus such as influenza, or for dengue in the tropics. Onset is usually sudden, with fever, headache, myalgias, malaise, and occasionally prostration. The same virus can cause a variety of clinical syndromes. Infection with some alphaviruses, such as VEEV, EEEV, and WEEV, may lead to more severe disease, such as encephalitis, often with a fatal outcome or permanent neurological sequelae. These and some other alphaviruses are also responsible for disease in animals, notably *Equidae*. Often only a small proportion of people infected with these potentially encephalitic arboviruses progress to overt encephalitis; most develop only the prodromal, nonspecific stage of the infection, which may even be asymptomatic.

PATHOGENESIS

In vertebrates, initial sites of replication include skeletal muscle (EEEV, WEEV, SFV, RRV, SINV, and Getah virus (GETV)), and Langerhans' cells in the skin, leading to infection of the draining lymph node (VEEV, and probably others) (Griffin, 2001a; 2001b; Tsai et al. 2002). Plasma viremia is probably the main form of dissemination to other tissues and organs. Viruses such as RRV that cause a rash replicate in the skin, and RRV and CHIKV are also believed to replicate in striated muscle. Experimental studies have shown that invasion of the central nervous system (CNS), when this occurs, generally follows initial virus replication in various peripheral sites and a period of viremia exceeding a threshold for CNS entry. Entry to the CNS through the olfactory tract has been demonstrated for VEEV in a mouse model, but has not been investigated for most alphaviruses, and pathogenesis in humans is very poorly understood. CNS invasion may also occur through endothelial cells.

Alphaviruses can also cause pathology in their mosquito vectors, though vector pathogenesis has only been investigated thoroughly in a few cases. WEEV and EEEV kill midgut epithelial cells, their initial sites of replication, and this pathology may hasten dissemination of virus from the midgut to the salivary glands by facilitating passage through the basal lamina. Although mosquito pathology reduces the survival of mosquitoes infected with EEEV, the late timing of mortality may result in little effect on virus transmission.

IMMUNE RESPONSE AND DIAGNOSIS

Alphaviruses are highly immunogenic, and both cellular and humoral immune mechanisms contribute to recovery following natural or experimental infection. Humoral immunity is believed to be more important for protection (Tsai et al. 2002).

Alphavirus infections are diagnosed on the basis of either immunoglobulin M (IgM) and immunoglobulin G (IgG) serological responses, or by isolation of virus from acute-phase serum. Serological tests commonly employed include IgM or IgG ELISA, plaque reduction neutralization, hemagglutination inhibition, or complement fixation. Virus isolation is readily accomplished using a variety of vertebrate cells, such as Vero or baby hamster kidney (BHK), or using mosquito cells such as C6/36. Intracranial inoculation of newborn mice is more sensitive than cell culture for some alphaviruses. Alphaviruses are seldom recovered from the CNS, including the cerebrospinal fluid (CSF), except from fatal cases. A large array of antialphavirus murine monoclonal antibodies is available for virus identification.

CONTROL OF ALPHAVIRAL DISEASE

Because most alphaviruses are maintained in zoonotic transmission cycles, little can be done in an ecologically acceptable manner to control levels of virus circulation. The interruption of transmission to humans by mosquito control provides the only effective approach to control most alphaviral diseases. Control of some alphaviral diseases such as EEE relies on early detection of enzootic amplification in reservoir hosts (e.g. birds), followed by mosquito control to reduce vector populations in inhabited regions. Sentinel animals can also be used to detect virus circulation, or testing of potential mosquito vector pools for virus infection. For equine encephalitides such as EEE and VEE, equine cases usually precede human infection by a few weeks, and are useful indicators of the need for vector control (Weaver 2001a, b).

Mosquito control to reduce vector populations usually relies on the large-scale application of adulticides – or sometimes larvicides – in regions of enzootic or epidemic transmission. The inaccessibility of many enzootic habitats necessitates aerial insecticide applications. For many alphaviral diseases, personal protection against mosquito bites is the most effective means of human disease prevention. This is especially important

for individuals who reside, work, or recreate near habitats known or suspected of harboring enzootic transmission. Diethylmethylbenzamide (DEET) (35 percent formulations recommended; 10 percent for children) is the most effective mosquito repellent generally approved for use on the skin, and permethrin can be applied to clothing and camping gear to enhance protection. Education of persons likely to contact enzootic habitats is also important for preventing human infection.

There are no licensed human alphavirus vaccines. Equine vaccines are available for EEEV, WEEV, VEEV, and GETV. For some alphaviruses, such as VEEV, that require equines for efficient amplification to infect large numbers of people, equine vaccination can be effective in limiting human disease.

ENCEPHALITIS AND OTHER IMPORTANT ALPHAVIRUS DISEASES

Eastern equine encephalitis

HISTORY AND DISTRIBUTION

EEEV was first isolated in 1933 from the brain of an infected horse, and in Argentina in 1930 (identified retrospectively). EEEV occurs in hardwood swamp habitats near the eastern seaboard, the Gulf coast, and at some inland midwestern locations of the USA, and in Canada, some Caribbean Islands, Mexico, and Central and South America (Scott and Weaver 1989; Weaver 2001a). Small outbreaks of human disease have occurred in the USA, the Dominican Republic, Cuba, and Jamaica. More extensive equine epizootics are common during the summer in temperate areas of the USA and Argentina, and as far north as Québec, Ontario, and Alberta in Canada. Four distinct antigenic variants representing distinct genetic lineages of EEEV have been delineated; three occur in Latin America and do not appear to cause human disease. The fourth is represented by all strains from North America and the Caribbean, and is highly virulent for people.

TRANSMISSION CYCLES

EEEV circulates nearly continuously in tropical and subtropical locations, and appears to overwinter in temperate areas of the USA by an unknown mechanism (Weaver 2001a). In North America, enzootic circulation involves passerine bird reservoir hosts and *Culiseta melanura*, an ornithophilic mosquito that is found in hardwood swamp habitats (Figure 3). The distribution of EEEV closely approximates that of *Cs. melanura*, suggesting that it is the principal enzootic vector. Larvae of *Cs. melanura* develop at the base of trees or under roots in swampy, peat soils. Because humans, equines, and most other animals apart from passerine birds are believed to be dead-end hosts, and *Cs. melanura* is probably by far the most efficient vector, human and equine cases are generally found in close proximity to swamp habitats; epizootic transmission probably involves bridge vectors such as *Coquillettidia perturbans*, *Ochlerotatus canadensis*, and *Oc. sollicitans*, which feed on both birds and mammals and can transmit to humans, horses, and other hosts. Other species, such as *Aedes vexans* in temperate regions and *Oc. taeniorhynchus*, *Culex taeniopus*, and *Cx. nigripalpus* in the tropics, may be involved in transmission to humans and equines. The EEEV transmission cycle in Latin America is poorly characterized, but probably involves enzootic vectors in the subgenus *Culex (Melanoconion)*, and possibly birds and rodents as reservoir hosts.

DISEASE AND VIRAL GENETICS

Although not well documented, rates of inapparent (encephalitis) infection suggest that most human EEEV infections result in a nonspecific prodromal illness characterized by fever, headache, myalgias, photophobia, and dysesthesias (Tsai et al. 2002). The incubation period is 4–10 days, and the prodromal phase evolves over several days to longer than a week before the onset of encephalitis in some patients, especially young children and the elderly. The development of encephalitis is typically accompanied by severe frontal headache, dizziness, vomiting, lethargy, and later, neck stiffness, confusion, delirium, and drowsiness, sometimes leading to coma. Patients may have other neurological disorders, such as abnormal reflexes, spasticity, paralysis, and cranial nerve palsies, and infants may have convulsions and bulging fontanelles. The CSF is under pressure, has elevated protein, and pleocytosis is common. EEEV infection is also accompanied by visceral and pulmonary congestion. In the brain, loss of neurons, perivascular cuffing, microglial proliferation, and focal inflammatory infiltration are the most typical findings of human encephalitis. Vascular lesions are also common, with thrombi and extravasation of red cells, and necrosis and demyelinization also occur. Apoptosis occurs in glial and inflammatory cells, but is less commonly associated with neuronal cell death. Overall mortality rates during more recent outbreaks have averaged about 33 percent.

An EEEV vaccine is not available for general human use, although formalin-inactivated vaccines are effective in horses if administered frequently.

Genetically and antigenically, EEEV is highly conserved in North America, where a single, highly conserved lineage has evolved since 1933 (Weaver 2001a). The North American strains have also caused outbreaks as far south as Mexico and the Caribbean. EEEV strains isolated in Latin America are more genetically and antigenically diverse. There is no evidence that Central/South American strains of EEEV

cause human encephalitis, or even a febrile illness. Detection of human antibodies in South America suggests that the explanation for the lack of human encephalitis cases there is related to a difference in human virulence between the North and South/Central American virus lineages.

Western equine encephalitis

HISTORY AND DISTRIBUTION

WEEV was first isolated in California in 1930 from the brain of a horse, and remains an important cause of encephalitis in *Equidae* and in humans in North America, mainly in western parts of the USA and Canada (Reisen 2001; Reisen and Monath 1988). Sporadic cases also occur in Central and South America.

TRANSMISSION CYCLES

In the western USA the enzootic cycle of WEEV occurs mainly during the summer and involves passerine birds, in which the infection is inapparent. *Cx. tarsalis*, a mosquito associated with agriculture and irrigation systems, is the principal vector (Figure 4). A summer cycle involving jackrabbits and *Ae. melanimon* or *Oc. dorsalis* mosquitoes has also been documented in desert environments. The mechanism of WEEV overwintering in temperate climates is unknown, but chronic infection of birds has been observed after experimental infection. WEEV has also been isolated from snakes and from a variety of mammal species. In Argentina, *Oc. albifasciatus* is a probable mosquito vector.

DISEASE AND VIRAL GENETICS

Human WEE cases are usually first seen in June or July in the northern hemisphere. Most WEEV infections are asymptomatic or present as mild, nonspecific illness with fever, headache, and fatigue. Patients with clinically apparent illness usually have a sudden onset, with fever, headache, chills, nausea, myalgia, vomiting, anorexia, and malaise, followed by altered mental status, weakness, dizziness, vomiting, and signs of meningeal irritation (Tsai et al. 2002). Some patients progress to neck stiffness, weakness, and generalized tremulousness, and occasionally stupor or coma. Children, especially those under 1 year old, are affected more severely than adults and may be left with permanent sequelae, which are seen in 5–10 percent of patients. Overall mortality in apparent cases is 4 percent and is highest among the elderly.

Several genetic lineages and antigenic subtypes of WEEV have been delineated. Interestingly, unlike EEEV, some lineages of WEEV range in distribution from North to South America, and others appear to be limited to the tropics or subtropics. Virulence differences have been detected in mice, but it is unknown whether there are differences in virulence for humans.

Venezuelan equine encephalitis

HISTORY AND DISTRIBUTION

VEEV was first isolated in Venezuela in 1938 from the brain of a horse; like EEEV and WEEV, it causes encephalitis in Equidae and humans. VEE is an important veterinary and public health problem in Central and South America because equines remain important for agriculture and transportation in many regions (Walton and Grayson 1988; Weaver 2001b). Focal outbreaks occur periodically, with some spreading over large areas and causing up to hundreds-of-thousands of equine and human cases. A large epizootic that began in Guatemala and El Salvador in 1969 reached Texas in 1971; it was estimated that over 200 000 horses died in that outbreak, which was controlled by a massive equine vaccination programme using the live-attenuated TC-83 vaccine. Several thousand human infections were documented. A more recent VEE epidemic occurred in the fall of 1995 in Venezuela and Colombia, with an estimated 100 000 human infections.

TRANSMISSION CYCLES

Epizootic transmission involves horses, mules, and donkeys as amplification hosts, and a variety of mosquitoes in the genera *Ochlerotatus*, *Psorophora*, and others as vectors. Although infected people become viremic and capable of amplification by infection of mosquito vectors, epidemiological evidence (lack of any major epidemics in the absence of equine amplification) indicates that they are not as efficient as equines; this is probably due to the fewer mosquitoes sustained by viremic persons than by equines. Although most human VEE cases occur during equine epizootics, endemic transmission also occurs in communities in close proximity to sylvatic enzootic cycles in the absence of any equine disease.

DISEASE AND VIRAL GENETICS

VEEV is one of several alphaviruses in the VEE antigenic complex (Table 1; Figure 1). Only VEEV and Everglades virus (genetically a variant of VEEV in subtype ID) are associated with encephalitis in humans, but other VEE complex viruses, such as Mucambo, can cause febrile illness. All major human and equine VEE outbreaks have involved subtype IAB and IC strains of VEEV, which are capable of efficient equine amplification via the production of high-titered viremia (Figure 5). These equine-virulent strains apparently evolve periodically from equine-avirulent enzootic strains in subtype ID. Some outbreaks from the 1940s to

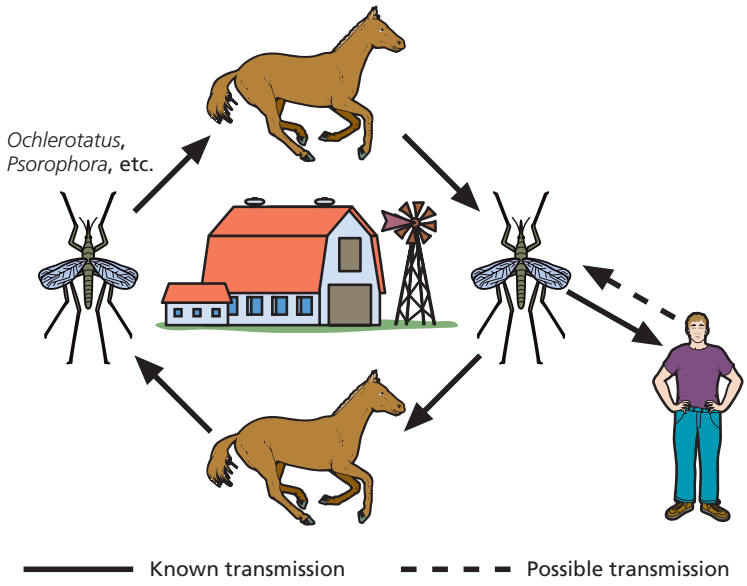

Figure 5 *Epizootic transmission cycle of Venezuelan equine encephalitis virus*

1973 may have been caused by the use of incompletely inactivated vaccines made from equine-virulent subtype IAB strains.

Enzootic strains (subtypes ID, and IE) of VEEV and all other members of the VEE complex occur in swamp or sylvatic habitats, ranging from southern Mexico to Argentina. These viruses are generally maintained in cycles involving forest-dwelling rodents and *Culex (Melanoconion)* spp. mosquito vectors. Occasional human cases or small outbreaks of human febrile illness occur when people come into contact with these enzootic cycles. The enzootic strains can also occasionally cause human encephalitis, and there may be no difference in human virulence between the epizootic (serotypes IAB and IC) and enzootic (serotypes ID and IE) VEEV strains.

In adults, VEEV infection typically leads to a nonspecific febrile illness accompanied by severe headache, fever, chills, myalgia, prostration, vomiting, diarrhea, and lymphopenia. Some patients, especially children, progress to neurological disease characterized by convulsions, disorientation, drowsiness, mental depression, seizures, and behavioral changes; permanent sequelae are common. Teratogenic effects and fetal death occur following infection in pregnant women. Infection is accompanied by diffuse congestion and edema, with hemorrhage in the brain, gastrointestinal tract, and lungs. Severe necrosis and vasculitis occur in lymph nodes, spleen, and the gastrointestinal tract, along with hepatocellular degeneration and interstitial pneumonia. During epidemics, overall mortality rates average about 0.5 percent. Although humans shed virus in the throat and are potentially infectious, epidemiological studies have failed to yield evidence of direct human–human transmission in households or healthcare settings.

Chikungunya

HISTORY AND DISTRIBUTION

Chikungunya virus (CHIKV) was first isolated from human patients and mosquitoes during an epidemic in the Newala district of Tanzania in 1952/53. The native name, which means 'that which bends up,' is derived from the main symptom of excruciating joint pains (Woodall 2001a; Jupp and McIntosh 1988). Chikungunya virus has frequently been isolated from humans and mosquitoes during epidemics in India, southeast Asia, southeast Africa and sub-Saharan Africa. The largest epidemics in recent years have been in India and Indonesia.

TRANSMISSION CYCLES

CHIKV is transmitted in Africa primarily by sylvatic *Aedes* spp., whereas *Ae. aegypti* transmits the virus in urban centres of India and southeast Asia. No vertebrate host other than humans has been discovered, although monkeys are probable reservoir hosts in Africa.

DISEASE AND VIRAL GENETICS

After an incubation period of 2–4 days there is a sudden onset of fever and crippling joint pains, which may incapacitate the patient, accompanied by chills, flushed face, headache, myalgias, backache, photophobia, and rash in ca. 80 percent of patients (Tsai et al. 2002). There may be conjunctival injection, and patients often have anorexia and constipation. The acute phase of illness lasts for 2–4 days, with recovery in 5–7 days; the fever may be biphasic. Arthralgia is the most striking sign or symptom, occurring in about 70 percent of cases. The areas affected include the metacarpophalangeal joints, wrists, elbows, shoulders, knees, ankles, and metatarsal

joints. Arthralgia may affect one or several joints. Reddening and swelling may occur, and arthralgias may persist for months in a small proportion of cases. The clinical picture resembles that of dengue fever, with which it is often confused. Differential diagnosis should include dengue, SINV, and West Nile virus.

In India and southeast Asia, Chikungunya virus has been implicated in outbreaks of hemorrhagic fever, often in association with dengue viruses. A careful review of the clinical presentation of CHIKV infection in Asia, however, suggests that, although mild hemorrhagic manifestations may occur in a small proportion of cases, Chikungunya is not a cause of severe hemorrhagic disease. Hemorrhagic complications have not been reported in association with Chikungunya infections in Africa. Phylogenetic studies and historical observations have suggested that CHIKV originated in Africa and spread to Asia from eastern Africa. Two distinct CHIKV lineages have been delineated: one contains all isolates from western Africa, and the second comprises all southern and East African strains, as well as isolates from Asia.

O'nyong-nyong

HISTORY AND DISTRIBUTION

This virus caused a major epidemic that began in Uganda in 1959 and quickly spread to Kenya, Sudan, Congo, Tanzania, Mozambique, and Malawi, affecting an estimated 2 million people and 90 percent of the population in affected areas (Woodall 2001b). A 1996 epidemic in Uganda affected more than 1 million people. The name O'nyong-nyong was given by the Acholi people and means 'joint breaker.' Igbo-ora virus, isolated in Nigeria, the Central African Republic, and the Ivory Coast during the 1960s, where it caused small outbreaks, is considered a genetic variant of O'nyong-nyong virus (ONNV). ONNV is closely related to CHIKV, and the diseases produced by the two agents are very similar. However, ONNV has a geographically limited distribution in Africa.

TRANSMISSION CYCLES

O'nyong-nyong virus is transmitted by *Anopheles gambiae* and *An. funestus* mosquitoes during outbreaks (it is the only anopheline-borne alphavirus), both of which also transmit malaria. The interepidemic maintenance cycle and reservoir hosts of ONNV have not been described, but the virus has been isolated from sentinel mice in Senegal in the absence of human disease (although human serosurveys indicated a prevalence of 55 percent there).

DISEASE AND VIRAL GENETICS

Infection with ONNV is clinically indistinguishable from that with CHIKV, and is accompanied by fever, chills, severe headache, myalgia, arthralgia, and the formation of a morbilliform rash. No human mortality has been reported.

Ross River fever

HISTORY AND DISTRIBUTION

Ross River virus (RRV) is the most common human arboviral pathogen in Australia, and over 38 000 human cases were reported between 1991 and 1998. Epidemics of benign polyarthritis have been recognized there since 1928, but the causative agent, RRV, was not isolated until 1959 from *Oc. vigilax* mosquitoes collected along the Ross River (Mackenzie 2001b; Kay and Aaskov 1988). Epidemics of polyarthritis involving several thousand cases have occurred regularly in Australia, and the virus is endemic in most coastal regions of the country, as well as inland, especially along waterways and rivers. Since the early 1980s RRV has possibly expanded its geographic distribution into the Pacific, with outbreaks in New Guinea, Fiji, American Samoa, Raratonga, Tonga, and New Caledonia.

TRANSMISSION CYCLES

The natural transmission cycle of RRV is not well understood. Serological surveys suggest that a diverse group of wild and domestic animals may be involved as reservoir hosts. Humans have significant viremia, and the virus in some epidemics has been maintained in a human–mosquito transmission cycle. In coastal regions, *Oc. vigilax* in the north and *Oc. camptorhynchus* in the south and west are important mosquito vectors. *Cx. annulirostris* is also considered an important vector in Australia. In the Pacific islands, *Ae. polynesiensis*, *Oc. vigilax* and *Ae. aegypti* are important vectors. Macropods (kangaroos) are believed to be the principal reservoir hosts in Australia, but other mammals, including flying foxes and rabbits, may also be involved.

DISEASE AND VIRAL GENETICS

Disease occurs most commonly in persons 20–50 years of age and is rare in children; women are affected more often than men. The incubation period is 5–21 (typically 7–9) days; patients with polyarthritis present with fever, arthralgia of the small joints of the hands and feet, myalgia, maculopapular or vesicular rash, paresthesiae of the palms and the soles, lethargy, and headache. Photophobia, anorexia, and lymphadenopathy may also occur. The painful arthritis frequently persists for several weeks, occasionally relapsing a year or more later, but recovery is complete and no fatalities have been reported. Subclinical infections also appear to be common. The persistence of IgM antibodies for several months after infection, and the detection of viral RNA in the synovial lining fluid by RT-PCR, suggest that replication may persist in joints, possibly associated with macrophages.

No vaccine is available. Prevention and control measures are directed at the mosquito population, and at health education on how to protect against mosquito bites. Two major RRV lineages have been identified phylogenetically, in eastern and western Australia, respectively; the eastern lineage caused the Pacific outbreaks in 1979–1980.

Other alphavirus infections

BARMAH FOREST VIRUS

First isolated in Australia from *Cx. annulirostris* mosquitoes, this virus accounts for about 10 percent of epidemic polyarthritis cases there and is second only to RRV as a human arboviral pathogen. The virus appears to be restricted to Australia, where it causes a disease characterized by fever, fatigue, arthritis, arthralgia, and rash that is clinically similar to that caused by RRV. Human infection with Barmah Forest virus (BFV) was first reported in 1986, and the first epidemic of human disease occurred in 1992 in the Northern Territory (Mackenzie 2001a). BFV cross-reacts with other alphaviruses, including RRV, by hemaglutination inhibition tests, but is distinct by complement fixation and neutralization tests.

Mammals, including marsupials, are believed to be the reservoir hosts and the virus has been isolated from a wide range of mosquito species: *Cx. annulirostris* appears to be the most widespread vector. In coastal regions, *Oc. vigilax* and *Oc. camptorynchus* are believed to be major vectors. Human infection occurs sporadically, with the majority of cases being reported from Queensland.

GETAH VIRUS

This virus was originally isolated in Malaysia from *Cx. gelidus* mosquitoes and *Cx. tritaeniorhynchus*. It is closely related to Sagiyama, Bebaru, and RR viruses, which are considered to be subtypes of Getah (Kumanomido 2001; Powers et al. 2001). Getah virus (GETV) is found throughout southeast Asia, including Japan, the Philippines, and Australia, but serological cross-reaction with RRV makes interpretation of serosurvey data difficult. GETV has not been associated with human disease, but causes severe encephalitis in horses in Japan. Antibodies have also been detected in humans, horses, and pigs, but the virus is not known to cause disease in the former two hosts. Pigs may serve as amplifying hosts during equine epizootics. GETV has been isolated from a wide variety of mosquito species, especially *Culex* spp. in Asia and Australia, and from *Aedes* spp. in Siberia.

MAYARO VIRUS

Mayaro virus (MAYV) is closely related to Chikungunya and O'nyong-nyong viruses and causes a similar illness characterized by fever, chills, headache, myalgia, and arthralgia, followed by a maculopapular rash. Arthralgia may persist for weeks or even months (Powers et al. 2001; Tesh et al. 1999). Isolated first in Trinidad from human serum in 1954, it was subsequently isolated from humans in Brazil, Colombia, French Guiana, Venezuela, Bolivia, Surinam, and Peru. Serological surveys also suggest that it occurs in Guyana, Panama, and Costa Rica. Little is known about the natural history of MAYV, but it has been isolated numerous times from *Haemagogus* spp. mosquitoes, suggesting a monkey–*Haemagogus* mosquito sylvatic transmission cycle. Evolutionary studies indicate that an ancestor of Una virus and MAYV, sister species, was introduced from the Old World, where all other members of the Semliki Forest antigenic complex occur (Powers et al. 2001).

SINDBIS VIRUS

Sindbis virus (SINV) has been designated as the prototype *Alphavirus*. It was first isolated in Egypt in 1953 but has a wide distribution in Africa, India, tropical Asia, Australia, and Europe (Griffin 2001b). Three major virus lineages have been identified by phylogenetic studies: a Paleoarctic/Ethiopian lineage, an Oriental/Australian lineage, and a distinct lineage from southwestern Australia. It rarely causes overt disease, but has been associated with febrile illnesses in Africa and India. SINV has a number of variants that have caused outbreaks of human illness in Sweden (Ockelbo disease), Finland (Pogosta disease), Russia (Karelian fever), and West and Central Africa (Babanki). Ockelbo, a SINV variant, causes fever characterized by rash. The disease is described under the names of Ockelbo disease in Scandinavia, Pogosta disease in Finland, and Karelian fever in the USSR. A single case with hemorrhagic manifestations and joint pains has been reported from Australia. SINV is maintained in enzootic cycles involving a variety of birds and mosquitoes of the genera *Culex*, *Aedes*, and *Culiseta*.

SEMLIKI FOREST VIRUS

Semliki forest virus (SFV) was isolated from *Aedes* mosquitoes collected in the course of yellow fever field studies in Uganda. Zingilamo (isolated from birds in the Central African Republic) and Me Tri (isolated from humans in Vietnam) viruses are considered strains of SFV. The virus has been used widely in laboratory studies and was regarded as nonpathogenic until it caused a single, fatal infection in a laboratory worker. Antibodies to SFV are commonly found in human serum collected from both East and West Africa, but no overt disease was recognized until 1987, when it caused a large outbreak of mild febrile illness in Bangui, Central African Republic. SFV may be maintained in a

monkey–*Aedes* mosquito cycle, and ticks may also be involved (Pfeffer 2001).

PROPERTIES OF THE VIRUSES

Introduction

Viruses of the family *Bunyaviridae* are enveloped, single-stranded RNA viruses with a tripartite genome. Approximately 300 distinct viruses are included in five genera of the family: *Orthobunyavirus*, *Hantavirus*, *Nairovirus*, *Phlebovirus*, and *Tospovirus*. Viruses of the same genus share structural, genetic, and antigenic characteristics, and often similar epidemiology. Many are arboviruses (arthropod-borne viruses), transmitted between vertebrate hosts (or plants in the case of tospoviruses) by blood-feeding mosquitoes, ticks, gnats, or thrips. A significant exception is the genus *Hantavirus*, whose known members are maintained in nature by chronically infected rodents, especially of the family *Muridae*, and are thought to be transmitted most commonly among rodents by bite and aerosol, and to humans by aerosol. Among the noteworthy hantaviruses are *Hantaan virus* and *Sin Nombre virus*, which were the first viruses known to cause hemorrhagic fever with renal syndrome and hantavirus pulmonary syndrome, respectively. Other human diseases caused by viruses within the family include California encephalitis and La Crosse encephalitis (*Orthobunyavirus*), sandfly fever and Rift Valley fever (*Phlebovirus*), Crimean–Congo hemorrhagic fever (*Nairovirus*), Oropouche fever (*Orthobunyavirus*), and others. Viruses of the genus *Tospovirus* are presently known only as plant pathogens. More than 360 plant species belonging to 50 families are known to be susceptible to infection with tospoviruses.

The history of viruses of the family *Bunyaviridae* parallels that of arbovirology. Before 1950, many viruses were investigated because of their ability to cause human disease. Thus, during the Second World War, much was discovered about sandfly fever viruses, because these viruses were responsible for significant morbidity among Allied troops stationed in the Middle East (Hertig and Sabin 1964). Sandfly (or phlebotomus) fever virus later became the prototype member of the genus *Phlebovirus*. A second complex of viruses destined to become a genus within the family also has links to military medicine. Viruses now known to be members of the genus *Hantavirus* played major roles in military campaigns in Asia, Yugoslavia, and Scandinavia during the Second World War, and again during the Korean conflict. Indeed, today these viruses continue to infect soldiers in the Balkans and elsewhere. Likewise, university researchers in California isolated the prototype strain of California encephalitis in the mid-1940s, setting the stage for the discovery of many other closely related viruses, including significant human pathogens like La Crosse virus. Investigations of the California antigenic group of bunyaviruses led to the discovery of many of the fundamental characteristics of the family: the pathogenic potential of some viruses, transovarial transmission as a method of epidemiological maintenance, and the molecular basis for our current understanding of the group (LeDuc 1987).

The type species of the family, *Bunyamwera virus*, was first isolated in Uganda from a pool of *Aedes* mosquitoes collected during studies of yellow fever (Smithburn et al. 1946). *Bunyamwera virus* was clearly unrelated either to *Yellow fever virus* or to any other arbovirus then known, but subsequent studies showed that it shares structural and biochemical properties with many other viruses that now make up the family (Smithburn

et al. 1946; Murphy et al. 1973; Bishop et al. 1980; Elliott 1990). In the 1950s, the Rockefeller Foundation founded a series of international research stations dedicated to the study of viral diseases of humans, and during this time many of the viruses now recognized as members of the family were first discovered. For example, the laboratory in Belem, Brazil, was the source of many viruses then grouped antigenically as the 'group C' arboviruses through the classic work of Clarke and Casals (group A viruses evolved to the genus *Alphavirus*, in the family *Togaviridae*, while the group B viruses have become the genus *Flavivirus* in the family *Flaviviridae*). The Bunyamwera, group C, *Guama*, *Simbu*, and other arboviruses were known for a time as the 'Bunyamwera supergroup,' then finally linked structurally and biochemically to form the genus *Bunyavirus*, family *Bunyaviridae*. Recently, the Bunyaviridae subcommittee of the International Committee of the Taxonomy of Viruses (ICTV) has proposed that the genus *Bunyavirus* be renamed *Orthobunyavirus* and this will be included in the Eighth Report of the ICTV due to be published in 2004. The Rockefeller Foundation-sponsored laboratories in Africa and India further contributed to the growing number of then known 'bunyaviruses'. Even today, newly recognized viruses isolated from arthropods or vertebrates are often found to be members of the family.

Classification

Viruses of the family *Bunyaviridae* are classified according to structural similarities, antigenic characteristics, common biochemical properties and, more recently, genetic homology. Five genera are now recognized, the largest being the genus *Orthobunyavirus*, with approximately 170 different viruses assigned to 18 groups (Table 1). The genus *Hantavirus* takes its name from *Hantaan virus*, the cause of hemorrhagic fever with renal syndrome. The hantaviruses are rapidly expanding in number, many 'new' viruses being identified by polymerase chain reaction (PCR) amplification of viral RNA obtained from field samples, but in several cases the actual viruses have yet to be isolated in a tractable form. At present, at least 26 serologically and/or genetically unique hantaviruses have been described, with many others almost certainly awaiting discovery (Table 2, p. 5). The genus *Nairovirus* is named after the virus of Nairobi sheep disease (Montgomery 1917), and contains more than 30 viruses in seven groups. The genus *Phlebovirus* has recently been expanded to include an earlier distinct genus, *Uukuvirus*, now merged with the phleboviruses on the basis of a common replication strategy and genetic similarities (Elliott et al. 1992). The most recent addition to the family is the genus *Tospovirus*, which takes its name from tomato spotted wilt virus. At present, this genus is limited to plant viruses and is transmitted by thrips (Thysanoptera). The *Tospovirus* genus encompasses at least 13 viruses, 11 of which are divided into two serogroups and two others that are serologically unrelated (Table 3, p. 6).

Within each genus, viruses were historically divided on serological characteristics into group, complex, virus, and subtype. 'Subtype' refers to viruses that can be serologically distinguished only with difficulty; named viruses can be easily distinguished; 'complex' refers to assemblies of viruses that are significantly cross-reactive; and 'group' or 'serogroup' encompasses complexes that are distantly related by serological activity (Peters and LeDuc 1991). More recent classification schemes have included the concept of a virus species, defined as a polythetic class of viruses. The interpretation of what constitutes a virus species is not consistent for each genus of the family, or among virus families in general.

Morphology and structure

Virions generally seem, by electron microscopy (EM), to be 80–120 nm spherical particles. Although pleomorphic particles are commonly observed by EM, such irregularity may be the result of desiccation, which occurs during specimen preparation, rather than inherent properties of viruses in the family (Hewlett and Chiu 1991). External features of the virions include a distinct bilaminar membrane, approximately 5 nm thick, and a fringe of surface projections approximately 5–10 nm long, comprised of the viral envelope glycoproteins, G1 and G2 (von Bonsdorff and Pettersson 1975; Hewlett and Chiu 1991) (Figure 1, p. 6). Recently, the *Bunyaviridae* subcommittee of the ICTV has proposed that G1 and G2 be renamed Gn and Gc due to difficulties in a common nomeclature across the different genera in the *Bunyaviridae*. As this nonemcalture has not been adopted yet, the glycoproteins will be termed G1 and G2 in this chapter. Because of differences in the G1 and G2 proteins of viruses in each genus, the characteristic appearance of virions varies. The surface area of the bunyavirus, La Crosse virus, was calculated to be able to accommodate from 4 700 to 12 000 tightly packed G1 and G2 proteins; however, estimates from EM studies suggest that only 270–1 400 proteins are present on a virion (Hewlett and Chiu 1991). The arrangement of the proteins, therefore, must include wide spacing between each heterodimer of G1 and G2. The most comprehensive study of surface structure and chemical composition for a virus in the family was performed with the phlebovirus Uukuniemi virus. The virion surface units of Uukuniemi virus appeared as penton–hexon clusters with a $T = 12$, $P = 3$ icosahedral surface lattice and with hexon–hexon distances of approximately 12.5–16 nm for stained viral particles and 17 nm for freeze-etched samples

Numbers in parenthesis indicate the total viruses within that taxon.

(von Bonsdorff and Pettersson 1975). The biochemical composition of Uukuniemi virus was estimated to be 2 percent RNA, 58 percent protein, 33 percent lipid, and 7 percent carbohydrate (Obijeski and Murphy 1977).

All viruses in the family have tripartite, single-stranded RNA genomes, with segments designated large (L), medium (M), and small (S). Each RNA is complexed with many copies of the viral nucleocapsid protein (N) to form three distinct ribonucleocapsids, which seem to be helical (von Bonsdorff et al. 1970; von Bonsdorff and Pettersson 1975). Terminal, complementary, nucleotide sequences are conserved on the L, M, and S segments for viruses within a particular genus and differ from those of viruses in other genera (Patterson et al. 1983; Collett et al. 1985; Schmaljohn et al. 1986a; Rönnholm and Pettersson 1987; Schmaljohn et al. 1987;

de Haan et al. 1990, 1991; Elliott et al. 1991; Kormelink et al. 1992a) (Table 4). Base pairing of these RNAs to form panhandle structures (Figure 2, p. 8) can result in noncovalently closed circular RNAs and nucleocapsids (Pettersson and Bonsdorf 1975; Obijeski et al. 1976; Hewlett et al. 1977; Raju and Kolakofsky 1989) (see Figure 1).

At least one each of the L, M, and S ribonucleocapsids are required for viral infectivity. However, equal numbers of nucleocapsids may not always be packaged

		L	8897	3′-UCUCGUUAGUCCAUUU	D10066

a) Sequences identical on all three genome segments are underlined.

in mature virions (Bishop and Shope 1979). Differing complements of ribonucleocapsids were suggested to be related to virion size differences noted by EM (Talmon et al. 1987). Varying amounts of virus complementary-sense RNAs (cRNAs) were also identified in virions, but the significance, if any, of this finding is not known (Raju and Kolakofsky 1989; Simons et al. 1990; Kormelink et al. 1992a).

In addition to N, G1, and G2, virions also contain a polymerase protein (L) that is needed to copy the negative-sense viral genome into messenger-sense RNA(s) (Ranki and Pettersson 1975; Bouloy and Hannoun 1976; Schmaljohn and Dalrymple 1983; Patterson and Kolakofsky 1984; Gerbaud et al. 1987a; Adkins et al. 1995) (see Figure 1). The exact placement of the L protein within virions is not known, but it is believed to be associated with each of the ribonucleocapsids.

Genome structure and function

The expression strategies of the L, M, and S segments of viruses in the five genera of the family *Bunyaviridae* include both similarities and marked differences (Figure 3, p. 9). All viruses encode their structural proteins (N, G1/G2, and L) in the S, M, and L cRNA, respectively. Viruses in each genus, except for those in the genus *Hantavirus*, also encode nonstructural proteins in their M and/or S segment vRNA or cRNA. The G1 and G2 proteins of all viruses are believed to be encoded as a polyprotein precursor that is cleaved cotranslationally, although direct evidence for this has been obtained only for phleboviruses (Ulmanen et al. 1981; Rönnholm and Pettersson 1987; Suzich and Collett 1988; Andersson et al. 1997a). The L segments of all viruses described to date encode only the L protein and have <200 nucleotides of noncoding information (Elliott 1989; Schmaljohn 1990; de Haan et al. 1991; Muller et al. 1991). There is no evidence for additional coding regions in either the L segment cRNA or the vRNA but see Nairoviruses below.

ORTHOBUNYAVIRUSES

Orthobunyaviruses produce both N and a nonstructural protein, NS_S, from overlapping reading frames found in the S segment cRNA (Gentsch and Bishop 1978; Cash et al. 1979; Bishop et al. 1982; Fuller and Bishop 1982; Akashi and Bishop 1983; Cabradilla et al. 1983; Fuller et al. 1983; Akashi et al. 1984; Bouloy et al. 1984; Elliott 1985; Gerbaud et al. 1987b). Only one S segment mRNA species was detected for the orthobunyaviruses; thus, a single mRNA must be used for translation of both N and NS_S (Bouloy et al. 1984; Patterson and Kolakofsky 1984; Eshita et al. 1985; Saeed et al. 2000). The orthobunyavirus M segment encodes an NS_M protein between coding information for G2 and G1 (Eshita and Bishop 1984; Lees et al. 1986; Grady et al. 1987; Fazakerly et al. 1988; Nakitare and Elliott 1993).

HANTAVIRUSES

Hantaviruses seem to have the simplest genome expression strategy of viruses in the family bunyaviridae, in that there is no clear evidence that nonstructural proteins are generated. The S segments of certain hantaviruses have an overlapping reading frame within N, which could encode a protein similar in size to that of the bunyavirus NS_S protein. However, such a protein has not yet been found (Parrington and Kang 1990;

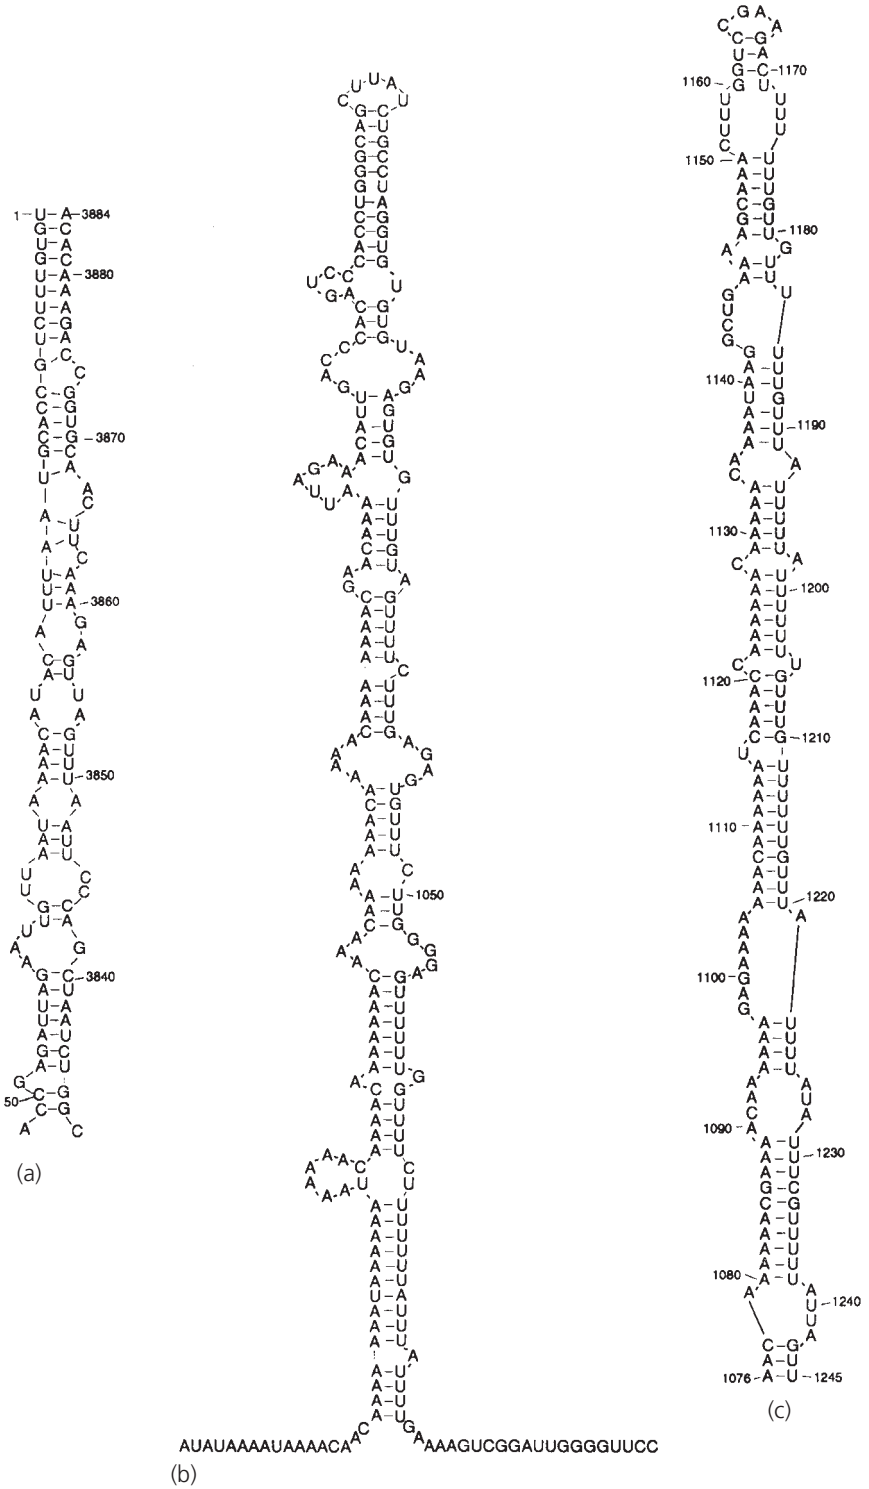

Figure 2 *Predicted panhandle structures formed by base-pairing of complementary sequences.* **(a)** *Terminal sequences of the M genome segment of the* Phlebovirus *Rift Valley fever virus (data from Collett et al. 1985).* **(b)** *Intergenic region of the ambisense S genome segment of the* Phlebovirus *Punta Toro virus (data from Emery 1987).* **(c)** *Intergenic region of the M genome segment of the* Tospovirus *Tomato spotted wilt virus (data from Kormelink et al. 1992b).*

Settergren et al. 1990; Stohwasser et al. 1990; Spiropoulou et al. 1994; Li et al. 1995). Certain of the New World hantaviruses have very large S segment 3′ noncoding regions; i.e. >700 bases for Sin Nombre virus as compared to <400 bases for prototype hantaan virus. Numerous repeated nucleotide sequences found in the

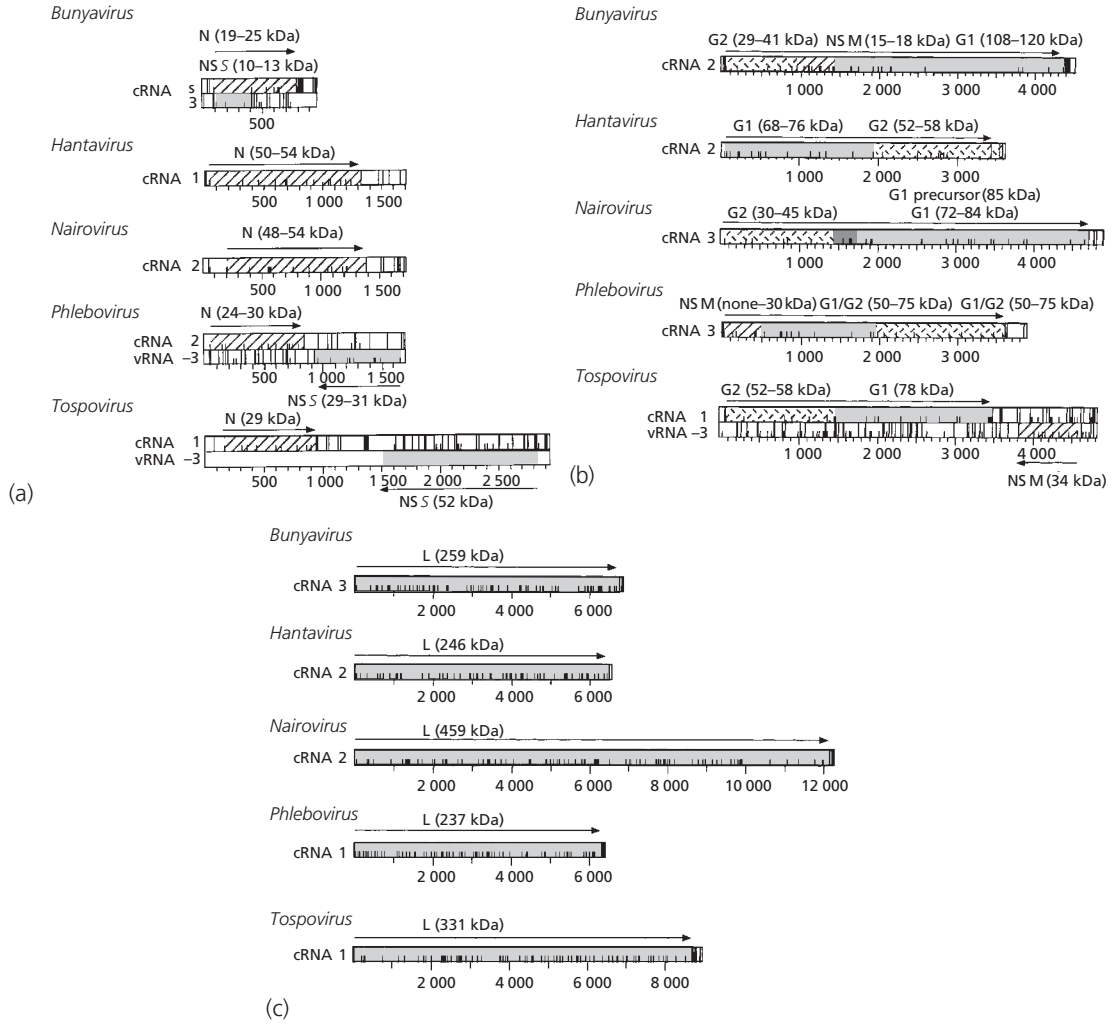

Figure 3 *Coding strategy and gene organization of the bunyaviruses.* **(a)** *S segment open reading frames encoding the N and NS$_S$ proteins are indicated by striped and stippled boxes, respectively.* **(b)** *M segment open reading frames encoding G1, G2, and NS$_M$ are indicated by stippled, cross-hatched and striped boxes, respectively.* **(c)** *L segment open reading frames encoding the L protein are indicated by stippled boxes. Translation initiation codons are represented by short hatch marks and stop codons are indicated by long hatch marks. The reading frame used, with respect to complementary sense RNA (cRNA, frames 1, 2, 3) or virus sense RNA (vRNA, frames –1, –2, –3) are listed to the left of the boxes. Nucleotide sequence numbers, with respect to the 5′ terminus of cRNA are shown below the boxes. Arrows indicate the direction of translation, 5′ to 3′, and predicted molecular weights of the gene products are shown above or below the arrows.*

Sin Nombre virus noncoding region are suggested to result from polymerase slippage, but a functional importance for their presence has not been discovered (Spiropoulou et al. 1994; Li et al. 1995; Morzunov et al. 1995; Ravkov et al. 1995). The M segments of hantaviruses have only a short potential intergenic region (e.g. $\leqslant$34 amino acids for Hantaan virus) between the sequences encoding G1 and G2, as well as little additional 5′ or 3′ noncoding information (Schmaljohn et al. 1987).

PHLEBOVIRUSES

Phleboviruses use an ambisense coding strategy to produce an NS_S polypeptide. That is, NS_S is encoded in vRNA in a reading frame that does not overlap the cRNA sequences encoding N (Ihara et al. 1984; Overton et al. 1987; Marriott et al. 1989; Simons et al. 1990; Giorgi et al. 1991). The existence of NS_S was verified in cells infected with numerous phleboviruses, including Uukuniemi virus, Rift Valley fever virus, Punta Toro virus, and Karimabad virus (Parker and Hewlett 1981; Ulmanen et al. 1981; Smith and Pifat 1982; Struthers and Swanepoel 1982; Overton et al. 1987). In vitro translation studies and northern blot analyses with viral RNAs demonstrated that N and NS_S are generated from separate, subgenomic messages (Ulmanen et al. 1981; Parker et al. 1984; Ihara et al. 1985b; Marriott et al. 1989; Simons et al. 1990). The M segment of some, but not all, phleboviruses encodes an NS_M in cRNA in the same reading frame but preceding the coding information for G1 and G2 (Collett et al. 1985). For example, the cRNA

open reading frame of Rift Valley fever virus has five in-frame translation initiation codons. Use of the first ATG resulted in production of uncleaved NS_M G2 as well as G1, whereas use of the second ATG resulted in distinct NS_M of approximately 14 kDa, G2 and G1 proteins (Collett et al. 1985; Suzich and Collett 1988; Kakach et al. 1989; Schmaljohn et al. 1989; Suzich et al. 1990). Both the NS_M G2 fusion protein and the NS_M protein are readily observed in cell cultures infected with Rift Valley fever virus. An even larger potential NS_M protein (approximately 30 kDa) with 13 inframe initiation codons is predicted from the M segment nucleotide sequence of Punta Toro virus. However, no polypeptide of this has been identified in cells infected with Punta Toro virus (Ihara et al. 1985a). There is no apparent homology between the Rift Valley fever virus and Punta Toro virus NS_M proteins, and both Rift Valley fever virus and Punta Toro virus G1 and G2 proteins can be efficiently produced in vitro in the absence of the NS_M coding information (Matsuoka et al. 1988; Suzich and Collett 1988; Suzich et al. 1990).

In contrast to those of Punta Toro virus and Rift Valley fever virus, the M segment of the phlebovirus, Uukuniemi virus, has no preglycoprotein coding region, and the amino terminus of G1 is located 17 amino acids downstream of the first (and only) initiation codon (Rönnholm and Pettersson 1987). Thus, Uukuniemi virus G1 seems to be similar to the Rift Valley fever virus NS_M G2 fusion protein. Cleavage of the G1/G2 precursor of Uukuniemi virus takes place cotranslationally in the endoplasmic reticulum, shortly after synthesis of G2 begins, and the G2 signal sequence remains attached to the carboxy terminus of G1 (Andersson et al. 1997a).

NAIROVIRUSES

The S segment of nairoviruses, like that of hantaviruses, encodes only a large N protein and has no known nonstructural protein coding information (Cash 1985; Ward et al. 1990; Marriott and Nuttall 1992). The M segment of the nairovirus, Dugbe virus, seems to encode only G2 and G1, although G1 was suggested to arise from post-translational cleavage of a slightly larger precursor (Marriott et al. 1992). The L segment of *Dugbe virus* is the largest gene of any member of the family bunyaviridae. Until recently it was not known why nairoviruses might need a polymerase protein almost twice the size of some of the other viruses in the family. Nucleotide sequencing of the L RNA of Crimean-Congo hemorrhagic fever virus revealed the segment is 12 164 nucleotides in length and encodes 3 944 amino acids. The amino terminus of the L protein encodes an ovarian tumorlike cysteine protease motif suggesting that the L polyprotein is autoproteolytically cleaved or involved in deubiquitination (Honig et al. 2004; Kinsella et al. 2004).

TOSPOVIRUSES

Both the S and the M segments of tospoviruses have ambisense coding strategies and separate subgenomic messages to generate structural and nonstructural proteins (de Haan et al. 1990; Kormelink et al. 1992a; Law et al. 1992). Unlike the NS_S of phleboviruses, which is about the same size as N, that of tospoviruses is approximately twice the size of N (Figure 3). Thus, the L segment of tospoviruses is the only one of the three gene segments that uses a strictly negative-sense coding strategy (de Haan et al. 1991).

Replication

ATTACHMENT AND ENTRY

One or both of the integral viral envelope proteins, G1 and G2, are believed to mediate attachment of virions to host-cell receptors. This was first demonstrated by proteolytic enzyme treatment of purified La Crosse virus, which resulted in 'spikeless' virus particles and a concomitant 5 $\log_{10}$ reduction in infectivity (Obijeski et al. 1976). For most viruses in the family, it is not known which of the envelope glycoproteins mediates attachment. To attempt to answer that question for bunyaviruses, La Crosse virus was treated with bromelain or Pronase, which degraded portions of G1, but left G2 uncleaved. Such treatment resulted in its complete loss of infectivity (Kingsford and Hill 1981). La Crosse virus G1 was also implicated as the attachment protein for mammalian cells because affinity-purified G1 protein could competitively inhibit attachment of radiolabeled G1 to Vero cells (Ludwig et al. 1991). In contrast, G2 did not bind to Vero cells, but did bind to cultured mosquito cells and midguts. To competitively inhibit binding of G2, both G1 and G2 were required, which led to the speculation that the G1 protein might be the viral attachment protein for vertebrates, whereas G2 is used for arthropod infection (Ludwig et al. 1991). Confirmation of this as a general feature of the bunyaviruses is needed. Although no similar information exists for viruses in other genera, there is evidence that neutralizing and hemagglutination-inhibiting (HI) sites are present on both the G1 and G2 proteins of phleboviruses (Keegan and Collett 1986; Pifat et al. 1988) and hantaviruses (Dantas et al. 1986; Arikawa et al. 1989), so it is possible that either or both of these proteins may be involved in attachment. Although cellular receptors have not been clearly identified for most viruses in the family, for two hantaviruses which cause hantavirus pulmonary syndrome, Sin Nombre virus and New York virus, integrins expressed on endothelial cells were implicated as specific receptors (Gavrilovskaya et al. 1998).

Fusion of infected cells at acidic pH has been reported for viruses in the *Bunyaviridae* (Gonzalez-Scarano et al. 1984; Arikawa et al. 1985; Gonzalez-Scarano 1985;

Gonzalez-Scarano et al. 1985). Such pH-dependent fusion is generally believed to relate to early events in internalization of viral particles. Electron microscopy of the infection process of Rift Valley fever virus revealed that virions seem to enter cells in phagocytic vacuoles (Ellis et al. 1988). This observation is consistent with a mode of entry similar to that first described for alphaviruses in which the virus is endocytosed in coated vesicles which subsequently become acidified (Marsh and Helenius 1980; Tycko and Maxfield 1982). The acidification triggers a fusion of viral membranes and endosomal membranes, and results in the release of the viral nucleocapsid into the cell cytoplasm. Whether one or both of the envelope proteins are necessary for fusion has not been determined for most members of the family. For the orthobunyavirus La Crosse virus, there is ample information to indicate that the G1 protein is involved in fusion. For example, it is known that monoclonal antibodies to G1 inhibit fusion, that G1 undergoes a conformational change at the pH of fusion and that a virus mutant with a defective G1 does not cause fusion (Gonzalez-Scarano 1985; Gonzalez-Scarano et al. 1985, 1987). Consistent with this, expression of G1 in the absence of G2 with recombinant vaccinia viruses resulted in cell fusion in vitro (Jacoby et al. 1993). These functions defined for the G1 and G2 proteins of bunyaviruses do not imply like functions for viruses in other genera.

TRANSCRIPTION

After uncoating of viral genomes, primary transcription of negative-sense vRNA to complementary mRNA occurs through interaction of the virion-associated polymerase (L protein) and the three viral RNA templates (Ranki and Pettersson 1975; Bouloy and Hannoun 1976). Transcription occurs entirely in the cytoplasm and there is no requirement for ongoing cellular transcription, as indicated by the resistance of viruses in the family to actinomycin D, an inhibitor of DNA-dependent RNA polymerases, such as host-cell DNA-dependent RNA polymerase II (Obijeski and Murphy 1977). Only the L and N proteins of Bunyamwera virus (Dunn et al. 1995) and Rift Valley fever virus (Lopez et al. 1995; Prehaud et al. 1997) were found to be necessary to reconstitute transcription in vitro. The L protein is believed to function first as an endonuclease to cleave capped oligonucleotides from host mRNAs to serve as transcription primers (Figure 4). This priming results in the presence of 5′ terminal extensions of approximately 10–18 heterogeneous nucleotides on the termini of viral mRNAs (Bishop et al. 1983; Bishop et al. 1984; Patterson and Kolakofsky 1984; Eshita et al. 1985; Ihara et al. 1985b; Collett 1986; Bouloy et al. 1990; Simons and Pettersson 1991; Kormelink et al. 1992c; Dobbs and Kang 1993; Jin and Elliott 1993a, b). For phleboviruses and tospoviruses, which have ambisense coding strategies, both the N and the NS_S subgenomic mRNA have heterogeneous, nonviral, 5′ terminal extensions (Ihara et al. 1985b; Simons and Pettersson 1991; Kormelink et al. 1992b).

Direct evidence for the presence of capped structures on the termini of the extensions was obtained by using anticap antibodies to immunoselect mRNAs (Hacker 1990; Vialat and Bouloy 1992). That the cleavage of capped oligonucleotides may not be an entirely random process is indicated by a preference for specific mono-, di- or trinucleotides at the −1 to −3 positions with respect to the 5′ terminus of mRNAs of particular viruses. For example, almost all cDNA clones of the S mRNA of the orthobunyavirus Germiston virus displayed U or G at the −1 position (Bouloy et al. 1990). Similarly, Bunyamwera virus preferred UG, but snowshoe hare virus was found to have A most commonly as the 3′ terminal nucleotide of the S mRNA extensions (Bishop et al. 1983; Eshita et al. 1985; Jin and Elliott 1993a). For phleboviruses, C was found most often at the –1 position of the M mRNA of Rift Valley fever virus and also at the –1 position of the N and NS_S mRNAs of Uukuniemi virus (Collett 1986; Simons and Pettersson 1991). For Hantaan virus, the preferred –1 nucleotide was G (Dobbs and Kang 1993; Garcin et al. 1995) and for the nairovirus Dugbe virus, C (Jin and Elliott 1993b). The reason for such preferences could imply that a restricted or specific subset of host mRNAs is used for primers, perhaps because of a need for limited base pairing with the viral genome.

Studies on the orthobunyaviruses Germiston virus and Bunyamwera virus revealed the insertion of U or GU between the primer and the 5′ terminal viral sequence. It was also noted that the 3′ most terminal nucleotides of the stolen host sequences were often similar to the 5′ terminal viral sequences, leading to the hypothesis that the insertions might arise from partial reiteration of the 5′ terminal sequences owing to a backward slippage of the viral polymerase after the first two or three nucleotides are transcribed (Vialat and Bouloy 1992; Jin and Elliott 1993a). In addition to such insertions, for orthobunyavirus and phlebovirus mRNAs, but not for the nairovirus mRNAs studied, the +1 nucleotide in the mRNA transcript is sometimes missing (Bishop et al. 1983; Bouloy et al. 1990; Simons and Pettersson 1991; Jin and Elliott 1993a, b), and for hantavirus RNAs the first three nucleotides are often absent (Dobbs and Kang 1993).These findings suggest that transcription initiation at nucleotides other than the terminal one may occur. For hantaviruses, a prime-and-realign-model for transcription was proposed which explains many of the experimental observations (Garcin et al. 1995). According to the model, priming by host oligonucleotides, with a terminal G residue would initiate transcription by aligning at the third nucleotide of the viral RNA template (C residue). After synthesis of a few oligonucleotides, the nascent RNA could realign by slipping backwards two nucleo-

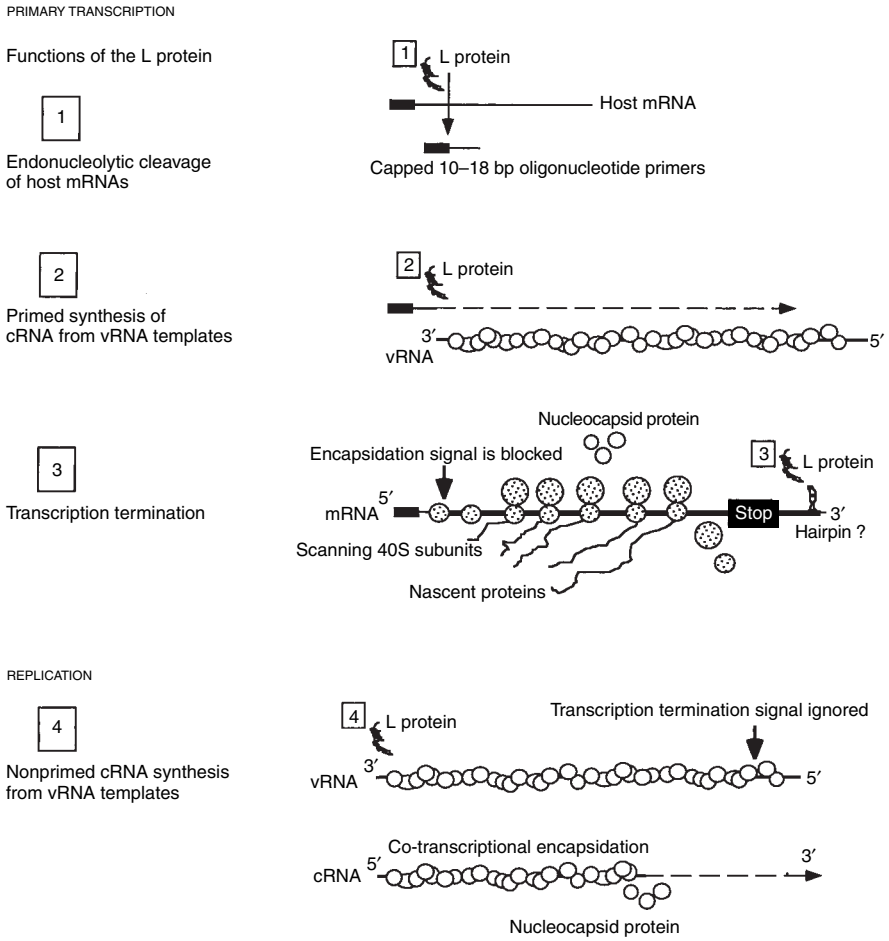

Figure 4 *Transcription and replication of the bunyaviruses. (1) The L protein cleaves capped oligonucleotides from host cell mRNAs. (2) The capped oligonucleotides are used to prime transcription of cRNA from vRNA templates. (3) Transcription is terminated at signals that may involve secondary structure or primary sequence of the vRNA template. mRNAs are not encapsidated, perhaps owing to the presence of scanning 40S ribosomes or the caps. (4) For replication to proceed, the L protein must use nonprimed synthesis and must ignore transcription termination signals to produce complete cRNA templates for further vRNA synthesis. The mechanism(s) of the switch from transcription to replication are not well defined.*

tides on the repeated terminal sequences (AUCAUCAUC), such that the G becomes the first nucleotide of the nontemplated, 5′ extensions. The frequent deletion of one or two of the triplet repeats in hantaviral mRNA supports this sort of slippage mechanism and suggests that sometimes the initial priming might start at the C residue of the third triplet in the conserved sequence rather than at the C of the second triplet. A prime-and-realign model was also suggested for transcription of hantaviral vRNA and cRNA, except that transcription is postulated to initiate with pppG alignment at the third nucleotide (C residue) of the template RNA. After synthesis of several nucleotides, the polymerase slips, allowing the nascent RNA to realign such that the initial priming G residue is overhanging. The L protein was suggested to act as an endonuclease to remove the G, leaving a monophosphorylated U residue at the nascent 5′ end. The presence of the monophosphorylated U on hantaan virus RNA was experimentally demonstrated (Garcin et al. 1995).

For the phlebovirus Rift Valley fever virus, a reconstituted transcription system was used to experimentally demonstrate that the minimal signal for transcription is the 13 3′-terminal nucleotides of the S segment vRNA or cRNA (Prehaud et al. 1997). One of the two repeated dinucleotides at the temini (UGUG) could be removed without deleterious effect on transcription, thus providing indirect support for the prime-and-realign model for phleboviruses, as well as hantaviruses. Whether this model holds for all viruses in the family remains to be determined.

At present, it is not clear what host functions are important for primary transcription of viruses in the family *Bunyaviridae*. Conflicting data concerning the need for ongoing host protein synthesis for primary transcription (as defined by the inability to achieve full length transcripts in the presence of drugs, such as cycloheximide and puromycin) were reported for viruses in the genus *Orthobunyavirus* (Abraham and Pattnaik 1983; Patterson and Kolakofsky 1984; Eshita et al. 1985;

Raju and Kolakofsky 1986, 1987a, 1989; Bellocq et al. 1987). If there is a need for ongoing protein synthesis, it may be at the level of ribosome scanning, rather than translation. This speculation was based on the finding that transcription was not inhibited by edeine, a drug that prevents 40S and 60S ribosomal subunits from complexing (Vialat and Bouloy 1992). These data are consistent with an earlier hypothesis that scanning ribosomes prevent premature termination by preventing base-pairing between the template RNA and the transcript, which would cause the polymerase to halt and terminate prematurely (Bellocq et al. 1987).

Termination of primary transcripts (i.e. mRNAs) occurs approximately 100 nucleotides from the 5′ terminus of the vRNA template, resulting in mRNAs that are truncated at their 3′ termini, as compared to cRNA (Figure 44) (Cash et al. 1979; Pattnaik and Abraham 1983; Bouloy et al. 1984; Patterson and Kolakofsky 1984; Eshita et al. 1985; Pettersson et al. 1985; Collett 1986; Raju and Kolakofsky 1987b; Bouloy et al. 1990). Potential transcription termination sites have been proposed for the S segments of La Crosse virus (Patterson and Kolakofsky 1984) and snowshoe hare virus (Eshita and Bishop 1984; Eshita et al. 1985) at or near the genomic sequence 3′-G/CUUUUU. Proposed U-rich transcription termination sites also are found on the M and S segments of Germiston virus (3′-AUGUUUUUGUU and 3′-GGGGUUUGUU, respectively) (Bouloy et al. 1990). Although such transcription termination sites are similar to those resulting in polyadenylation of mRNAs of other viruses, mRNAs of viruses in the family *Bunyaviridae* are not known to be polyadenylated (Ulmanen et al. 1981; Pattnaik and Abraham 1983; Pettersson et al. 1985). Moreover, transcription termination sites without the homopolymeric U_5 or U_6 tract have been proposed for the S and M segment mRNAs of another orthobunyavirus, snowshoe hare virus (5′-GGUGGGGGGUGGGG and 5′-GGUGGGGGGUGGGG, respectively) (Eshita and Bishop 1984) and the M segments of the phleboviruses Rift Valley fever virus and Punta Toro virus (5′-UGGGGUGGUGGGGU and 5′-GGUGAGAGUGUAGAAAG, respectively) (Collett 1986). Comparing the S segment sequences of a number of phleboviruses revealed that G-rich sequences and similar sequence motifs were found in the intergenic regions of some, but not all, phleboviruses (Giorgi et al. 1991).

Transcription termination of ambisense genes to yield structural and nonstructural protein mRNAs may occur through recognition of RNA secondary structure rather than a specific gene sequence. For example, the transcription termination sites for both the N and the NS_S mRNAs of Punta Toro virus were mapped to within 40 nucleotides of one another, and predicted hairpin structures were found in this intergenic region, as well as in the intergenic regions of the S segments of certain other phleboviruses and in both the S and the M segments of tospoviruses (de Haan et al. 1990; Kormelink et al. 1992b; Law et al. 1992) (see Figure 3). For the S segment of the phlebovirus Uukuniemi virus, although there is a noncoding region of 70 nucleotides between the N and the NS_S genes, hybridization studies demonstrated that the 3′ ends of the subgenomic messages overlap one another by about 100 nucleotides. Thus the 3′ end of the NS_S mRNA extends into the coding region of N and the 3′ end of the N mRNA terminates just before the coding sequences for N. A short palindromic sequence in the intergenic region (including the 3′ ends of each mRNA) is predicted to allow formation of an A/U-rich hairpin structure (Simons and Pettersson 1991). Such structures could affect transcription termination only if they can form while the genome is complexed with N. To date there is no direct evidence that this occurs.

Although the mechanism of transcription termination is not known, studies performed with the L protein of Bunyamwera virus expressed by vaccinia virus recombinants resulted infrequently in correct transcription termination, suggesting that an additional factor (or factors), of viral or cellular origin, may be required for consistent transcription termination (Jin and Elliott 1993a). One such factor might include interaction between the transcriptase and a newly synthesized viral protein, such as NS_S (Vialat and Bouloy 1992; Jin and Elliott 1993a). This could not be a familial characteristic, however, because hantaviruses and nairoviruses are not known to encode NS_S proteins. Also, for viruses using ambisense coding to produce NS_S, the kinetics of synthesis of N and NS_S, as well as the finding that only N mRNA can be detected in the presence of cycloheximide, suggest that replication of full-length, encapsidated cRNA must occur before synthesis of the NS_S mRNA. Thus, because NS_S appears relatively late in infection, it is unlikely to have a role in primary transcription, unless it can be generated in small amounts directly by translation of the vRNA (Simons et al. 1992).

GENOME REPLICATION

The switch from primary transcription to genome replication requires the L protein to switch from primed synthesis, by using capped host-cell oligonucleotides, to a process of independently initiating transcription at the precise 3′ end of the template and producing an encapsidated, full-length transcript. The factors dictating that vRNA and cRNA should complex with N to form nucleocapsid structures, while mRNAs should not, are not known, but it has been suggested that the added capped host cell sequences on the 5′ ends of viral messages may somehow prevent encapsidation (Raju and Kolakofsky 1989).

Unlike primary transcription, secondary transcription is clearly sensitive to inhibitors of protein synthesis, such

as cycloheximide. The need for ongoing protein synthesis for replication to proceed is likely to be due to the need for continued viral protein synthesis rather than host cell protein synthesis. Although the factors that dictate that the L protein should begin genome replication are not known for viruses in the family *Bunyaviridae*, a mechanism similar to that proposed for rhabdoviruses and paramyxoviruses seems plausible: accumulating a sufficient quantity of N seems to trigger encapsidation and to serve as an antitermination signal, thus allowing full-length genome synthesis (Blumberg et al. 1983; Wertz 1983; Patton et al. 1984a, 1984b; Arnheiter et al. 1985; Banerjee 1987; Vidal and Kolakofsky 1989). Nonstructural proteins were suggested to control the availability of the N protein of rhabdoviruses, and where available, they could possibly do the same for the *Bunyaviridae*. A model for transcription and replication based on information detailed above is presented in Figure 4.

SYNTHESIS AND PROCESSING OF VIRAL PROTEINS

S segment gene products

As described above (Orthobunyaviruses, Phleboviruses, Tospoviruses), the N and NS_S proteins encoded by the vRNA and cRNA of the S segments of bunyaviruses, phleboviruses, and tospoviruses do not originate from precursor polypeptides, and therefore processing of proteins is not required. Hantaviruses and nairoviruses encode only one product in their S segments. Post-translational modifications (e.g. phosphorylation or amidation) have not generally been defined for S segment products except for the NS_S of Rift Valley fever virus. For Rift Valley fever virus, the NS_S protein was reported to be phosphorylated (Parker et al. 1984) and to accumulate in the nuclei of infected cells where they seemed to aggregate as filamentous structures (Struthers and Swanepoel 1982). Although this is not known to be a general finding for phleboviruses, very few of them have been examined with immune sera specific for the NS_S protein. The NS_S of the tospovirus tomato spotted wilt virus was seen in association with fibrous structures in the cytoplasm of infected plants. However, it was not clear if the proteins actually formed the filaments or were just associated with them (Kormelink et al. 1991).

The NS_S protein has been found to function as an interferon antagonist and also inhibit host-cell protein synthesis (Bouloy et al. 2001; Bridgen et al. 2001). A detailed description of its function can be found in the Antigens, immune responses, and virulence section below.

M segment gene products

Historically, the designation of glycoproteins G1 and G2 comes from their relative migrations when analyzed by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE). G1 is the more slowly migrating polypeptide. These designations, based on apparent polypeptide size, do not always correlate with the gene order, structure or function of G1 and G2. For example, for the two phleboviruses Rift Valley fever virus and Punta Toro virus, it is known that G1 of Rift Valley fever virus is related to G2 of Punta Toro virus and vice versa (see Figure 3). Thus, the terms Gn and Gc have been proposed by the *Bunyaviridae* subcommittee of the ICTV to overcome problems with nomenclature, but have yet to be universally adopted.

Cotranslational cleavage of G1 and G2 (and in the *Bunyavirus* and *Phlebovirus* genera, NS_M) is believed to be mediated by a cellular signalase-like enzyme. Except for the *Nairovirus* Dugbe virus, which may encode G1 as a precursor, all predicted polyprotein precursors have hydrophobic regions preceding both G1 and G2 that are consistent with signal sequences that allow transport of the nascent proteins through membranes. The precursors also have variable numbers of potential transmembrane regions, and a hydrophobic sequence at the carboxy terminus, indicative of a membrane anchor region (Eshita and Bishop 1984; Collett et al. 1985; Schmaljohn et al. 1987; Fazakerley and Ross 1989; Law et al. 1992; Marriott et al. 1992). Thus, these proteins are assumed to be typical class 1 membrane proteins, i.e. with the amino terminus exposed on the surface of the virion and the C terminus anchored in the membrane.

A common property of all M segment gene products predicted from cDNA sequences studied so far is their high cysteine content (4–7 percent) and, in related viruses, the conservation of the position of the cysteine residues (Ihara et al. 1985a; Lees et al. 1986; Grady et al. 1987; Rönnholm and Pettersson 1987; Antic et al. 1992b; Kormelink et al. 1992b; Law et al. 1992; Marriott et al. 1992). These findings suggest that extensive disulfide bridge formation may occur and that the positions may be crucial for determining correct polypeptide folding. The secondary structure of the proteins can also play a role in immunogenicity, in that neutralizing or protective epitopes are often conformational and nonlinear (Battles and Dalrymple 1988; Wang et al. 1993).

All of the envelope proteins examined to date possess *N*-linked oligosaccharides. The gene sequences that define a potential *N*-linked glycosylation site are those that encode Asn–X–Ser/Thr, where X is not Pro (Hubbard and Ivatt 1981). The number of potential glycosylation sites found in the predicted M segment gene product range from four sites for certain hantaviruses to nine sites for some tospoviruses (Antic et al. 1992b; Law et al. 1992). The number of sites actually used in mature virion proteins has not been defined for most viruses. However, G2 of the phlebovirus Rift Valley fever virus was demonstrated to be glycosylated at its single available site and at least three of four possible G1 sites (Kakach et al. 1989). Analysis of the

predicted amino acid sequences of the envelope proteins of the bunyavirus snowshoe hare virus (Eshita and Bishop 1984; Fazakerly et al. 1988) and examination of glycosylated tryptic oligopeptides (Vorndam and Trent 1979) suggest that all three potential glycosylation sites on G2 are used and at least one of two sites on G1. The single glycosylation site available in the G2 protein of hantaan virus is used, and this site is conserved among numerous other hantaviruses (Schmaljohn et al. 1986b; Antic et al. 1992a). Where studied, the oligosaccharides attached to the G1 and G2 proteins were mostly high-mannose glycans, although complex and novel intermediate-type oligosaccharides were also identified on the G1 protein of Uukuniemi virus (Madoff and Lenard 1982; Pesonen et al. 1982; Schmaljohn et al. 1986b; Antic et al. 1992a; Ruusala et al. 1992).

Although not studied extensively, the NS_M proteins of the bunyavirus Bunyamwera virus and the phlebovirus Rift Valley fever virus were found not to be glycosylated (Lees et al. 1986; Collett et al. 1989; Kakach et al. 1989). For Rift Valley fever virus, however, another M segment gene product consisting of an uncleaved form of the NS_M protein and G2 is also routinely generated, and the NS_M portion of that fusion protein is glycosylated (Kakach et al. 1989). The NS_M protein of tospoviruses is not a membrane protein. It is encoded in the ambisense and is translated from a subgenomic message. Because this protein has no counterpart in any of the other genera of the family, it was suggested to be a genetic adaption of these viruses for survival in plant hosts (Kormelink et al. 1994; Storms et al. 1995).

L segment gene products

No post-translational modifications of L proteins for viruses in the *Bunyaviridae* have been described. The L protein is a multifunctional enzyme. For Bunyamwera virus and Rift Valley fever virus, the L and N proteins are essential and sufficient for transcriptase activity (Dunn et al. 1995; Lopez et al. 1995). The Bunyamwera virus L protein transcribes a synthetic template in concert with the N proteins of closely related bunyaviruses, but only inefficiently with more dissimilar orthobunyavirus N proteins (Dunn et al. 1995). The complementary terminal nucleotide sequences of viruses in the family *Bunyaviridae* that are predicted to form panhandle structures have been suggested as possible polymerase recognition structures. Although only limited information exists, in one study a point mutation resulting in disruption of the base-paired structure was found to drastically reduce Bunyamwera virus L transcriptase activity in vitro (Dunn et al. 1995).

Comparison of L protein sequences of viruses in the family *Bunyaviridae* with other RNA polymerases revealed the presence of four conserved 'polymerase motifs' (Poch et al. 1989; Jin and Elliott 1992). Mutational analysis of cDNA representing Bunyamwera virus L within these conserved regions was used to demonstrate that amino acid residues that are highly conserved among viruses in the family could not be changed, but that changes in nonconserved amino acids did not generally reduce the ability of the expressed L protein to transcribe authentic viral nucleocapsid templates in an in vitro assay (Jin and Elliott 1992; Dunn et al. 1995).

TRANSPORT

One of the earliest notable features found to distinguish bunyaviruses from all other negative-strand RNA viruses was that the viral particles are formed intracellularly by a budding process at smooth surface vesicles in the Golgi area (von Bonsdorff et al. 1970; Lyons and Heyduk 1973; Murphy et al. 1973; Bishop and Shope 1979). Recent studies with Uukuniemi virus indicated that viruses mature not only in the Golgi stacks, but also in the pre-Golgi intermediate compartment (Jäntti and Hilden 1997). Because the virus particles are too large to be transported in the 60-nm vesicles postulated to function in the intra-Golgi transport network, it was suggested that the Golgi cisternae themselves may be involved in virion transport (Jäntti and Hilden 1997). The site of virus maturation, be it either the intermediate compartment or the Golgi stacks, is at least partly dictated by the accumulation and retention of a sufficient concentration of the viral envelope proteins. The factors involved in Golgi transport and retention have been studied for viruses in the genera *Phlebovirus*, *Hantavirus*, and *Orthobunyavirus*. For most of these viruses, it appears that dimerization of the two envelope proteins in the endoplasmic reticulum must occur before they are transported to the Golgi. For Punta Toro virus, kinetic studies indicated that heterodimerization occurs between newly synthesized G1 and G2 within 3 min after protein synthesis and that the dimers are linked by disulfide bonds (Chen and Compans 1991).

For phleboviruses, orthobunyaviruses, and some hantaviruses, if dimerization does not occur, then only one protein can move to the Golgi (Matsuoka et al. 1988, 1991; Chen and Compans 1991; Rönnholm 1992; Ruusala et al. 1992). For example, in the absence of G1, G2 of Punta Toro virus was transported out of the ER and expressed on the cell surface. Removal of the carboxy-terminal anchor sequence of G1 resulted in secretion of this protein. When both proteins were expressed, however, both G1 and G2 were found in the Golgi. These studies suggest that the Golgi transport and retention signal is located on the G1 protein of Punta Toro virus (Chen et al. 1991). Similar results were obtained with the phlebovirus Uukuniemi virus, in that expression of G1 and G2 independently in COS cells resulted in translocation of only G1 to the Golgi, while G2 remained in the ER, suggesting that the signal for transport resides on G1 and that G2 is transported only by association with G1 (Rönnholm 1992).

Conclusive evidence that the region of the cytoplasmic tail adjacent to the transmembrane domain is the Golgi retention signal for phleboviruses was obtained by expression of truncated and chimeric G1 proteins of Punta Toro (Matsuoka et al. 1994, 1996) and Uukuniemi viruses (Andersson et al. 1997b). In these studies, deleting or replacing the cytoplasmic tail of G1 resulted in cell surface expression, rather than Golgi retention. Also, addition of the cytoplasmic domain to proteins normally expressed at the plasma membrane effected Golgi retention. For Punta Toro virus, the retention signal was found to be located within the first ten amino acids of the cytoplasmic domain (Matsuoka et al. 1996). Similar studies have yet to be reported for viruses in other genera of the *Bunyaviridae*.

Although Golgi retention is the norm for G1 and G2 proteins of viruses in the family, some viruses mature at cell surface membranes. For two New World hantaviruses, Sin Nombre virus and Black Creek Canal virus, envelope glycoproteins were detected on the cell surface, and virus budding from the plasma membrane was observed by electron microscopy (Goldsmith et al. 1995; Ravkov et al. 1997). Likewise, even though the phlebovirus Rift Valley fever virus matures in the Golgi in continuous cell lines, in primary rat hepatocytes budding was observed at the plasma membrane in addition to Golgi membranes (Anderson and Smith 1987). The molecular basis for these observations has not yet been determined.

For bunyaviruses and phleboviruses, which express an NS_M protein in addition to G1 and G2, all three proteins localize in the Golgi. However, NS_M is not needed for transport, as indicated by targeting of G1 and G2 to the Golgi even when they were expressed from an M segment from which the NS_M coding region had been deleted (Matsuoka et al. 1988; Wasmoen et al. 1988; Lappin et al. 1994).

The transport of tospovirus proteins within plant cells and insect cells has not been studied extensively. These viruses replicate in insects (Ullman et al. 1993; Wijkamp et al. 1993), as well as plants. Therefore, in addition to possessing the transport mechanisms described for other arthropod-borne viruses in this family, tospoviruses must also be able to traverse the plant cell wall. For tomato spotted wilt virus, the NS_M protein was found to be associated with nucleocapsid aggregates and was postulated to be involved in cell-to-cell movement of nonenveloped ribonucleocapsids (Kormelink et al. 1994). The NS_M protein was further shown to assemble into tubule-like structures that were postulated to penetrate the plasmodesmata, allowing transport of the free, nonenveloped ribonucleocapsids from cell to cell (Storms et al. 1995). The association of NS_M only with nucleocapsids, but never with mature enveloped particles (Kormelink et al. 1994) supports this hypothesis. Thus it is likely that the G1 and G2 proteins (and envelope) of tospoviruses are required for replication in their insect vectors, but not in plants (Verkleij and Peters 1983; de Resende et al. 1991).

PROTEIN INTERACTIONS IN VIRUS ASSEMBLY AND RELEASE

Unlike viruses in families such as the *Rhabdoviridae*, *Orthomyxoviridae*, and *Paramyxoviridae*, which utilize their matrix (M) protein to act as a nucleating step for assembly and to bridge the gap between the integral viral envelope proteins and their nucleocapsids, bunyaviruses that do not have an M protein must rely on direct interaction of the envelope proteins and ribonucleocapsids to trigger assembly (Smith and Pifat 1982). Because viral ribonucleocapsids and spike structures have been observed only on portions of Golgi vesicle membranes directly involved in the budding process and not on adjacent areas of the same membranes, it is likely that some sort of transmembranal recognition between the viral glycoproteins and the N protein is required for budding. Direct evidence for transmembrane regions of G1 and G2 was obtained by enzymatic digestion of exposed proteins of the phlebovirus Karimabad. In this study, it was determined that approximately 12 percent of G1 or G2, or both, was exposed on the cytoplasmic face of membranes in infected cells and was accessible to digestion. A large protease-resistant fragment was identified, which was presumably sequestered in the membrane in a manner that rendered it safe from enzymatic digestion (Smith and Pifat 1982). Candidate transmembrane regions have been predicted from hydropathic characteristics of derived amino acid sequences representing the envelope proteins of all members of the *Bunyaviridae* examined to date. For Uukuniemi virus, it has been suggested that the cytoplasmic tail of G1 (which is at least 70 residues long) is a logical candidate for interaction with the nucleocapsids (Rönnholm and Pettersson 1987; Pettersson 1991).

This cytoplasmic tail was found to be palmitylated. Although removal of palmitylation sites (cysteine residues) had no effect on the transport of G1 to the Golgi, it is conceivable that such fatty acid acylation of the cytoplasmic domain could play a role in virus assembly, perhaps by facilitating interaction with N, but this remains to be experimentally determined (Andersson et al. 1997b).

It is believed that, after the particles bud into the Golgi cisternae, they are released in individual small vesicles in a manner analogous to secretory granules of other cell types (Broadwell and Oliver 1981; Rothman 1981; Smith and Pifat 1982). The release of virus from infected cells presumably occurs when the cytoplasmic, virus-containing vesicles fuse with the cellular plasma membrane, i.e. by normal exocytosis.

Host factors involved in transport of viral proteins have not been clearly defined. However, for Black Creek Canal virus, an interaction of nucleocapsid protein with cellular actin filaments was identified and

was suggested to play a role in virus assembly or release (Ravkov et al. 1998). Because this virus is atypical of most other viruses in the family (i.e. it buds at the plasma membrane instead of in the Golgi), it is not known if this finding will prove relevant to other members of the *Bunyaviridae*.

The morphogenesis of tospoviruses in their insect vector, thrips, seems to be similar to that observed with other viruses in the family (Wijkamp et al. 1993). Differences, however, are seen in plants and plant cells. As indicated above, it is likely that the tospovirus envelope is needed only for replication in insects, and not in plants. Nonenveloped tospovirus particles are commonly seen in infected plants (Kitajima et al. 1992); defective tomato spotted wilt virus isolates, which are defective in glycoprotein synthesis and lack the lipid envelope, were found to retain the ability to spread through plant tissues at the same rate as nondefective viruses (Verkleij and Peters 1983; de Resende et al. 1991). These findings, as well as the small pore size (approximately 3 nm) of plants' plasmodesmata, suggest that infectious ribonucleocapsids, rather than complete tospovirus virions, are transported through the plant plasmodesmata (Kormelink et al. 1994).

Antigens, immune responses, and virulence

The major viral antigens are the structural proteins, N, G1, and G2. Generally, the N protein is highly antigenic, and is usually the prominent antigen detected in serological assays such as complement fixation and ELISA of infected cell-culture lysates. The G1 and G2 proteins are the basis for serological assays such as hemagglutination inhibition and plaque-reduction neutralization.

For all animal-infecting bunyaviruses, the envelope glycoproteins, G1 and G2, are presumed to be the major antigens involved in induction of immunity. Three lines of evidence support this assumption: (1) monoclonal antibodies to G1 or G2 or both, but not to N, can neutralize viral infectivity in vitro; (2) passive transfer of neutralizing, but not nonneutralizing, monoclonal antibodies or monospecific polyclonal sera to G1 or G2 or both, protects animals from challenge with homologous viruses; and (3) immunization of animals with recombinant viruses expressing G1 or G2 (or both) results in protective immunity (Dantas et al. 1986; Collett et al. 1987; Pifat et al. 1988; Arikawa et al. 1989, 1992; Dalrymple et al. 1989; Schmaljohn et al. 1990; Pekosz et al. 1995). For some viruses, such as the phlebovirus Rift Valley fever virus, although monoclonal antibodies to both G1 and G2 will neutralize virus in cell culture, only those specific for G2 were able to passively protect animals. Passively transferred polyclonal, monospecific sera to G2 were also found to be protective, but sera to G1 were not (Dalrymple et al. 1981, 1989; Keegan and Collett 1986; Smith et al. 1987). This finding was substantiated in mice immunized with recombinant vaccinia or baculoviruses expressing either G1 or G2, in that only the G2 recombinants induced a protective immune response in the animals (Dalrymple et al. 1989; Schmaljohn et al. 1989). These findings suggest that a humoral response alone to one or both of the envelope glycoproteins may be sufficient for protection from infection with viruses in the family.

Little information is available concerning the importance of cell-mediated immune responses to members of the *Bunyaviridae*. For the hantavirus, Hantaan virus-specific cytotoxic T lymphocytes (CTL) were demonstrated after restimulation of immune mouse lymphocytes with Haantan virus antigen in vitro. The CTL response was also suggested to be involved in cross-reactive protection among hantaviruses. Evidence for this was obtained by restimulating, with Hantaan virus, spleen cells from mice immunized with heterologous hantaviruses. In one instance of cross-protection (i.e. immunization with Puumala virus and protection against Hantaan virus), evidence suggested that T cells may be particularly relevant (Asada et al. 1987, 1988, 1989). A non-neutralizing, presumbably cell-mediated, protective immune response was also demonstrated in hamsters immunized with baculovirus-expressed Hantaan virus and challenged with virulent Hantaan virus (Schmaljohn et al. 1990).

Recent studies have investigated the early immune response to bunyavirus infection. The type I interferon system, that includes protein kinase R (PKR), 2′–5′ oligoadenylate synthetase/RNase L and Mx proteins, has been shown to be important for antiviral activity by blocking transcription, translation, and replication of viral RNA, including sequestion of the N protein by the Mx protein (Frese et al. 1996; Kanerva et al. 1996; Jin et al. 2001; Kochs et al. 2002; Bridgen et al. 2004) and interferon knockout mice are susceptible to La Crosse virus infection, whereas wild-type mice are not (Hefti et al. 1999). Investigation of the function of the NSs protein of phleboviruses and orthobunyaviruses has shown that this viral protein is an interferon antagonist and has a critical function of suppressing the production of interferon in virus-infected cells. Initial studies with Rift Valley fever virus showed that a strain containing a deletion in the NSs gene was attenuated and a good interferon inducer, while wild-type virus was virulent and a poor interferon inducer (Vialat et al. 2000; Bouloy et al. 2001). Thus, NSs is an important virulence factor for members of the *Bunyaviridae*. Subsequent studies using reverse genetics of Bunyamwera virus showed that mutation of NSs resulted in a virus that induced high levels of interferon, whereas wild-type virus did not (Bridgen et al. 2001; Weber et al. 2002). These studies also suggested a role for NSs in the shutoff of host-cell protein synthesis that has been substantiated by Colon-Ramos et al. (2003) who have shown the

orthobunyavirus NSs has sequence and functional activities similar to Reaper, a proapoptotic protein from *Drosophila*, including inhibition of host-cell protein synthesis. Investigation of the mechanism of action of NSs shows that NSs blocks an early step in interferon induction, namely activation of interferon transcription factors NF-κB and interferon regulatory factor 3 (IRF-3) by double-stranded RNA (dsRNA) (Weber et al. 2000; Weber et al. 2002). Kohl et al. (2003) showed that virus lacking a functional NSs induces apoptotic cell death more rapidly than wild-type virus. Although both wild-type and NSs mutant viruses activated proapoptotic transcription factor IRF-3, only wild-type virus suppressed signaling downstream of IRF-3, thus delaying cell death via IFR-3-mediated apoptosis. However, although Bunyamwera virus NSs blocks induction of interferon by dsRNA, unlike other interferon antognists, it does not appear to involve the dsRNA-activated PKR and RNase L systems (Streitenfeld et al. 2003).

In recent years animal models have been developed for hantavirus pulmonary syndrome (Hooper et al. 2001b; Milazzo and Eyzaguirre 2002) and phlebovirus hemorrhagic fever (Fisher and Tesh 2003) that will be important in elucidating the pathogenesis of bunyavirus diseases.

For tospoviruses, resistance to infection was achieved by transforming plants with viral nucleoprotein (*N*) gene sequences (de Haan et al. 1992b; Vaira et al. 1995). This protection was demonstrated to be RNA-mediated, i.e. gene silencing owing to the presence of *N* gene sequences rather than to the presence of N protein (de Haan et al. 1992b; Pang et al. 1997). In addition to immunogenicity, the viral envelope glycoproteins are also most frequently associated with virulence, although this asssociation is not absolute. By using reassortant viruses, it was demonstrated that both mouse virulence and mosquito infectivity correlated with the M segment gene products of the bunyavirus, La Crosse virus (Gonzalez-Scarano et al. 1988). However, a study of reassortants of the phlebovirus Rift Valley fever virus revealed that attenuating mutations (for mice) were present in a vaccine strain virus on all three of the genome segments (Saluzzo and Smith 1990).

CLINICAL AND PATHOLOGICAL ASPECTS

Clinical manifestations

Over 60 viruses of the family *Bunyaviridae* are known to cause disease in humans or animals. Most human infections are silent, and are detectable only by the appearance of specific antibodies. When clinical disease occurs, manifestation of infection ranges from self-limited febrile disease to potentially fatal fulminant hemorrhagic fever or encephalitis. Acute undifferentiated illness is often characterized by an abrupt onset of fever, usually accompanied by chills. Myalgia, arthralgia, headache with or without photophobia, malaise, anorexia, and nausea are common; occasionally vomiting also occurs. Gastrointestinal symptoms rarely dominate the clinical picture, however, nor are respiratory symptoms often seen, although some patients may have sore throat, cough, or even pulmonary infiltrates. A notable exception is hantavirus pulmonary syndrome. Physical examination may reveal conjunctival injection, mild adenopathy, and some abdominal tenderness. Clinical laboratory findings usually indicate a normal, decreased, or moderately elevated white blood count. The typical duration of uncomplicated illness is 2–4 days, perhaps extending to a week. A second wave of fever may occur ('saddle-back fever'), but there is no residual illness seen, although convalescence may require several days.

More severe infections may include a maculopapular rash on the trunk appearing after the onset of illness and lasting a few days (Bwamba, Oropouche, and others), bleeding (most severe in Crimean–Congo hemorrhagic fever, Garissa fever, and Rift Valley fever), encephalitis (Bhanja, California group and Rift Valley fever), hepatitis (hantaviruses and Rift Valley fever), acute kidney failure (hantaviruses), aseptic meningitis (Bwamba, Oropouche, and others), respiratory distress due to acute pulmonary edema (New World hantaviruses) and retinal vasculitis (unique to Rift Valley fever). Fatal infections have often been associated with California group viruses, especially La Crosse virus in children, Crimean–Congo hemorrhagic fever, hantaviral infections, especially hantavirus pulmonary syndrome in which case fatality rates approach 50 percent, and Rift Valley fever virus.

The most important veterinary pathogens are akabane virus, the cause of congenital malformations and abortions in cattle, sheep, and goats in Japan, Australia, South Africa, and Israel (Parsonson and McPhee 1985), Aino, Cache Valley, and Nairobi sheep disease viruses, the cause of malformations and abortions in sheep and/or cattle. Rift Valley fever virus, in addition to human infections, also causes abortion and death in domestic animals. Rift Valley fever virus is commonly found throughout subSaharan Africa, with periodic epizootic/epidemic transmission in Egypt (Meegan 1979), Yemen, and Saudi Arabia (Shoemaker et al. 2002).

IMPORTANT INFECTIONS

California encephalitis and related viruses

California encephalitis was until 2000, the most important arboviral disease seen in the USA, the vast majority of cases being detected among children infected with La Crosse virus. For example, in 1996–1997, of the 286 confirmed or probable arboviral infections, 252 (88 percent) were caused by California group viruses. In those years, the greatest number of cases occurred in

West Virginia (139 cases) with 11 other states having at least one case (Report 1998). Other pathogenic California group viruses include prototype California encephalitis virus, Guaroa, Inkoo (Jamestown Canyon), snowshoe hare virus and Tahyna virus. With the exception of Inkoo and Tahyna viruses, California group viruses are found predominantly in North America where they are transmitted by mosquitoes. Inkoo and Tahyna viruses are found in Europe, and there is serological evidence to suggest that viruses similar or identical to snowshoe hare virus are present in Asia. Tahyna-related viruses have been found in Africa. California group viruses are widely distributed, being found from the tropical zones to above the Arctic Circle (reviewed in LeDuc 1979).

The incubation period for California encephalitis patients is about 3–7 days after an infectious mosquito bite. Onset is abrupt with fever, headache, and lethargy; nausea and vomiting are common. Rash, diarrhea and arthralgia are uncommon. In milder cases, recovery occurs within a week, the only indication of neurological involvement being meningeal signs and perhaps disorientation. More severe cases develop seizures, convulsions, and loss of consciousness, with coma in some instances. Mild neurological signs, which may still be present at discharge, manifest as irritability and other conditions, but usually resolve over the course of several weeks, with little in the way of permanent illness being reported. Of 166 cases reported, two died and two had lasting hemiparesis. Patients with seizures during acute disease are at greater risk for subsequent convulsions, usually seen within a year after recovery. Intellectual and social functions do not seem to be disturbed among recovered children (Matthews et al. 1968; Sabatino and Cramblett 1968; Grabow et al. 1969; Rie et al. 1973). La Crosse encephalitis is usually a disease of children, whereas Jamestown Canyon encephalitis is found in adults.

Tahyna virus is found primarily in Europe, with a related or identical virus being found in Africa (Lumbovirus). Antibodies in humans have been found in Sri Lanka, China, and Russia. Human infection ranges from a mild febrile disease to aseptic meningitis. Pharyngitis, pulmonary involvement, or gastrointestinal disturbances, such as nausea and vomiting may be common. Although CNS involvement has been documented, serious illness or death has not been associated with Tahyna virus infections (Peters and LeDuc 1991).

Akabane virus

Akabane virus is an important veterinary pathogen causing congenital malformations, arthrogryposis, hydranencephaly, and other deformities, as well as abortions in cattle, sheep, and goats in Japan, Australia, South Africa, and Israel (Parsonson and McPhee 1985). Antibodies to akabane virus have been found in sera collected from 25 of 41 wildlife species in 11 subSaharan African countries (Al Busaidy et al. 1987). Both *Culex* mosquitoes and *Culicoides* are implicated in transmission.

Oropouche fever virus

Oropouche virus was first isolated in Trinidad from the blood of a forest worker with a mild febrile illness. Although never common in Trinidad, the virus has become a major cause of rural and urban epidemics in the Amazon region of South America, a large percentage of the resident population being infected during outbreaks. More than 500 000 cases have been recorded, primarily from the Brazilian states of Para, Amazonas, Maranhao, and Goias and more recently from Peru, Panama, Bolivia, and Costa Rica (Vasconcelos et al. 1989, 1994; Watts et al. 1997; Saeed et al. 2000). The disease is characterized by headache, fever, myalgia, arthralgia, photophobia, retrobulbar pain, nausea, and dizziness. Rash occurs in less than 10 percent of the confirmed cases. Symptoms may recur in more than half those clinically ill, usually within 1–2 weeks of the initial onset. No deaths have been reported for Oropouche fever, but meningitis or meningismus has been reported. Patients are often debilitated and prostration is common (reviewed in LeDuc and Pinheiro 1988).

Hantavirus infections

Hemorrhagic fever with renal syndrome (HFRS) has long been recognized clinically in Asia, Russia, and Scandinavia, but the etiology of the syndrome has been known only since the late 1970s. Over 200 synonyms have been used to describe HFRS, including Korean hemorrhagic fever, epidemic hemorrhagic fever, nephropathia epidemica, epidemic nephrosonephritis, and many others, often referring to geographic locations. It was not until 1978, however, that the causative agent, hantaan virus, was isolated from the lungs of the striped fieldmouse, *Apodemus agrarius* (Lee et al. 1978). Unlike other members of the family *Bunyaviridae*, the hantaviruses that infect humans are maintained in nature by chronically infected rodents. No arthropod vector is involved in their transmission cycle. Hantaan virus was named after the Hantaan River, near the demilitarized zone dividing the Korean peninsula, where the infected field mice were first captured.

Subsequent studies have demonstrated that hantaan virus represents an antigenically and genetically novel virus among the *Bunyaviridae* and was thus the prototype member for a new genus within the family (Schmaljohn and Dalrymple 1983; Schmaljohn et al. 1985). Subsequently, additional serologically related viruses have been isolated, many of which are known to cause human disease. Previously, human disease was thought to be limited to febrile illness followed by varying

degrees of kidney failure. Recently, however, a new clinical presentation has been documented: hantavirus pulmonary syndrome (Duchin et al. 1994). This syndrome is characterized by acute onset of febrile disease, followed by an often fatal respiratory distress syndrome. Recent studies have shown this new disease to be caused also by hantaviral infections, but with a unique group of antigenically and genetically related viruses found only in the Americas. Thus, it appears that two basic lineages of hantaviruses have evolved, one occurring predominantly in the Old World, specifically evolving with rodent species found there, and leading to hemorrhagic fever with renal syndrome presentations, and one in the New World causing hantavirus pulmonary syndrome, maintained in nature by New World rodent species (Figure 5; and see Table 2).

Phylogenetic studies suggest that the hantaviruses can be divided into three main groups: the Hantaan-like viruses that are carried by Murinae rodents (Old World mice and rats), Puumala-like viruses that are carried by Arvicolinae rodents (lemmings and voles), and Sin Nombre-like viruses that are carried by Sigmodontinae rodents (New World mice and rats) (Plyusnin 2002). However, a number of these 'viruses' are classified solely on genetic data for a portion of the genome in the absence of virus isolation and few serologic studies (see Table 2). No doubt more detailed studies on these viruses will become available in the future.

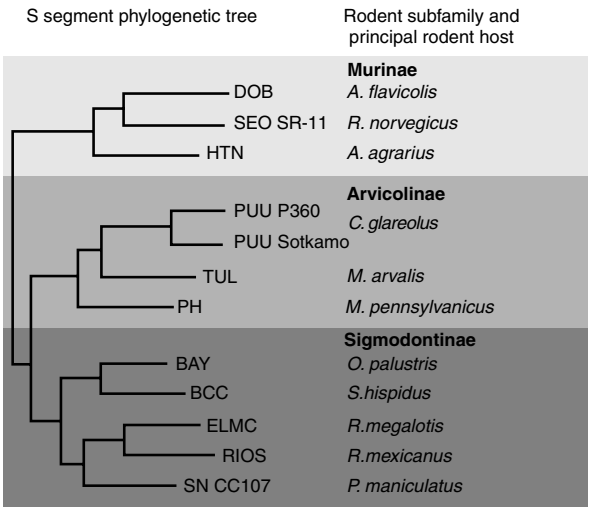

Figure 5 *Relationships of hantaviruses and their rodent hosts. Phylogenetic relationship of the complete S segments of hantaviruses is represented in a single most parsimonious tree derived by using PAUP 3.1.1 software. Horizontal lengths of branches are proportional to nucleotide sequence differences. Abbreviations for viruses and accession numbers for the S segment viral sequences are:* Dobrava virus*, DOB, L41916;* Seoul virus*, SEO, M34881;* Hantaan virus*, HTN, M14626;* Puumala virus*, PUU virus (strain P360), L11347; PUU (strain Sotkamo), X61035;* Tula virus*, TUL, Z30941;* Prospect Hill virus*, PH, X55128;* Bayou virus*, BAY, L36929;* Black Creek Canal virus*, BCC, L39949;* El Moro Canyon virus*, ELMC, U11427;* Rio Segundo virus*, RIOS, U18100;* Sin Nombre virus *(strain CC107) SN, L33683.*

The most severe form of HFRS occurs in Asia and is caused by prototype hantaan virus. It is associated with a case-fatality rate of approximately 5 percent, although this may be much higher in certain rural areas. This disease is characterized by an abrupt onset of fever, chills, malaise, myalgia, headache, dizziness, and anorexia after a variable incubation period of 2–42 days, but most often of 2–4 weeks. During this initial febrile phase, severe abdominal and back pain appear, accompanied by increasing nausea and vomiting, tenderness over the lower back, flushing of the face, neck and chest, and injection of the conjunctivae, palate, and pharynx. Petechiae may appear on the axillae, face, neck, chest, and soft palate, and hemorrhages into the conjunctivae may occur. Clinical laboratory studies reveal normal or slightly elevated white blood cell counts, decreased platelets and rising hematocrit (packed cell volume) values. Proteinuria may appear towards the end of this phase of the disease (McKee et al. 1985).

Defervescence occurs after 3–7 days and marks the start of the hypotensive phase, which may last from several hours to a few days. This phase is characterized by tachycardia, falling arterial pressure, and narrowing pulse pressure, mental changes and, in severe cases, classic shock. Bleeding tendencies continue with capillary hemorrhage and rising hematocrit values. Leukocytosis with a left shift, thrombocytopenia, and prolonged bleeding times are seen; there are high levels of proteinuria and oliguria begins. About one-third of the fatalities occur during this phase. The oliguric phase follows and lasts for 3–7 days, during which blood pressure returns to normal or is slightly elevated due to relative hypervolemia. The fall in urinary output is accompanied by elevated serum creatinine and blood urea nitrogen and other evidence of renal failure. Pulmonary edema may occur and care must be taken in fluid management. Rash and facial flushing disappear during this phase, although nausea and vomiting may continue. Severe hemorrhagic manifestations may occur, gastrointestinal or CNS bleeding being especially serious. Almost half the deaths occur during this phase, often due to pulmonary edema or infection, electrolyte imbalance, late shock, or hemorrhage into the brain. Clinical recovery begins during the diuretic phase, with the normalization of clotting and return of renal function. For the next few hours or days there is diuresis, with outputs of 3–6 liters daily. Strength and appetite improve, but fluid management must be maintained to prevent negative fluid balances which may lead to shock. The convalescent phase may require several months, and hyposthenuria may persist for months to years (McKee et al. 1985). Although complete recovery has been assumed, recent studies with Seoul virus have called this assumption into question (Glass et al. 1993). Specific therapy is not available, and careful supportive care is

essential to improving survival. Care must be consistent with the phase of the disease, careful attention being paid to fluid management. Recent studies have demonstrated that ribavirin is efficacious in treating HFRS if administered early in the course of illness (Huggins et al. 1991). Treated patients had significantly fewer deaths than those untreated, and they spent less time in each phase of the disease and were more likely to skip entire phases altogether.

Other Old World hantaviruses cause diseases similar to, though generally less severe than, classic hantaan virus infections. These include Puumala virus, the cause of nephropathia epidemica of western Europe, Scandinavia, and the western portions of Russia. Nephropathia epidemica may follow the same phases as classic HFRS, but is fatal in less than 1 percent of cases.

The severity of the clinical course of HFRS caused by Puumala virus was found to correlate statistically with specific HLA haplotypes, indicating that host, as well as virus, factors can dictate the outcome of hantaviral infection (Mustonen et al. 1996, 1998). In the Balkan region of Europe, Puumala virus overlaps in many areas with both classic hantaan virus and local strains that are capable of causing very severe disease with mortality rates at least as high as those seen in Asia. The severe HFRS of the Balkans has been associated with Dobrava virus, also reported as Belgrade virus (now known to be the same viruses) and is indistinguishable clinically from HFRS of Asia (Gligic et al. 1992; Avsic-Zupanc et al. 1992a, 1992b, 1995; Taller et al. 1993). Seoul virus, associated with *Rattus norvegicus* (brown rat), probably originated in Asia, but is now found throughout the world wherever large populations of rats exist (LeDuc et al. 1986). It causes a less severe form of HFRS that is characterized by greater liver involvement than classic Hantaan infections, and in general a lower case-fatality rate, although deaths have been recorded. Seoul virus infections are especially common in China, but have been documented in many parts of the world, including Europe and the Americas. In the USA, careful studies have associated past Seoul virus infection with an increased risk of hypertensive renal disease (Glass et al. 1993), an observation that could have significant economic implications for many developed countries (LeDuc et al. 1992).

Hantavirus pulmonary syndrome was first recognized in 1993, when an outbreak of an apparently new and highly fatal form of severe respiratory illness occurred in southwestern USA. As a result of subsequent field and laboratory investigations, the epidemiology and clinical characteristics of this new disease were described, and the name hantavirus pulmonary syndrome was proposed. It was caused by a previously unknown hantavirus, later named Sin Nombre virus (also reported as Four Corners or Muerto Canyon virus). The overall case-fatality rate was 52 percent and examination of the first 100 cases found they were distributed between 21 states. Furthermore the disease had been recognized since at least 1959 (Khan et al. 1996).

Hantavirus pulmonary syndrome has a prodrome of fever and myalgia (all of 17 patients originally described), with cough or dyspnea (76 percent), gastrointestinal symptoms (76 percent) and headache (71 percent) (Duchin et al. 1994). Physical characteristics seen among these original 17 cases include tachypnea (100 percent), tachycardia (94 percent), and hypotension (50 percent). Laboratory findings reflect leukocytosis, increased hematocrit, thrombocytopenia, prolonged prothrombin, and partial thromboplastin times, elevated serum lactate dehydrogenase, decreased serum protein concentrations, and proteinuria. Fifteen (88 percent) cases rapidly progressed to acute pulmonary edema, and 13 (76 percent) died. Predictors of death included increases in hematocrit and partial thromboplastin time, and all deaths occurred with profound hypotension (Duchin et al. 1994). Despite laboratory evidence strongly suggestive of disseminated intravascular coagulopathy, clinical signs of hemorrhage have rarely been reported (Zaki et al. 1995). Radiographic examination reveals bilateral pulmonary infiltrates in virtually all hospitalized patients, and pleural effusions in many. At postmortem examination, copious pleural effusions are often found (Zaki et al. 1995). Multiorgan involvement was found in all of 44 fatal cases examined, with generalized vascular congestion. The primary histopathological features were seen in the lung where microscopic examination revealed mild to moderate interstitial pneumonitis with variable degrees of congestion, edema, and mononuclear cell infiltrates (Zaki et al. 1995). Immunohistochemical examination of postmortem tissue from 44 fatal cases revealed viral antigen-positive cells widely distributed in various tissues, but seen predominantly within endothelial cells of capillaries and small vessels. The most intensive and extensive endothelial staining was in tissues of the lungs, where viral antigen was abundant and uniformly distributed. It involved most of the pulmonary microvasculature, although high densities of viral antigens were also observed in lymphoid follicles of the spleen and, to a lesser extent, in lymph node follicles (Zaki et al. 1995). The magnitude and extent, however, of pulmonary endothelial involvement reflect the difficulty experienced by clinicians in attempting to manage the often terminal shock syndrome.

Treatment has been prompt hospitalization, aggressive clinical management, and early pulmonary support. Ribavirin, which can be efficacious in the treatment of HFRS patients, has been administered to hantavirus pulmonary syndrome patients, but at present there are insufficient data to indicate efficacy clearly.

Crimean–Congo hemorrhagic fever virus

Crimean–Congo hemorrhagic fever (CCHF) is a severe, tickborne, acute hemorrhagic fever found throughout

much of Africa, extending northward to Albania, the former Yugoslavia, Crimea, and elsewhere in the former Soviet Union, Iraq, and much of the Middle East, and eastward into Pakistan and western China. Clinical disease has been well described from cases seen in the former Soviet Union, and nosocomial outbreaks have been common among hospitalized patients, especially those undergoing surgery. The case–fatality rate originally described for cases occurring in Crimea was 15–30 percent (Chumakov 1946); other outbreaks have had case–fatality rates as high as 40 percent (Hoogstraal 1979). Cases usually occur singly among shepherds or others with rural exposure who have been fed on by ticks, or as small clusters among individuals involved in the slaughter of an infected animal (Swanepoel et al. 1985). Nosocomial outbreaks have occurred in the former Soviet Union, the former Yugoslavia, South Africa, and the Middle East (Burney et al. 1976). They typically involve a severely ill patient with hemorrhage and a suspected acute abdomen, perforated ulcer or other diagnosis leading to surgical intervention. Inevitably the patient dies, and often the medical team, family members, or both, are infected, often with a fatal outcome.

The clinical picture of CCHF is an initial influenza-like illness followed by severe headache, joint and back pains, fever, nausea, vomiting, and photophobia. The incubation period is typically 3–6 days in nosocomial infections, and 3–12 days following tick exposure. Initial symptoms may be followed by circulatory collapse, shock, and a variety of hemorrhagic manifestations, such as epistaxis, hemoptysis, hematemesis, melena, and skin hemorrhage. Bleeding into the intestinal tract may cause the patient to present with acute abdominal pain, leading to surgical intervention and increased risk of nosocomial spread. Involvement of the central nervous system indicates a poor prognosis. Clinical laboratory data include leukopenia from the onset of illness, neutropenia, thrombocytopenia, and falling hemoglobin and erythrocyte counts in severely ill patients. The clinically apparent attack rate was estimated to be five infections per case of hemorrhagic fever in the former Soviet Union (Goldfarb et al. 1980).

Nairobi sheep disease virus

This acute, hemorrhagic gastroenteritis affecting sheep and goats in East Africa was described by Montgomery (1917), who correctly attributed transmission to the tick, *Rhipicephalus appendiculatus*. The case–fatality rate may be 70–90 percent in sheep, but goats are less seriously affected. Herdsmen tending infected animals may develop a mild, febrile illness, and laboratory infections with this virus have occurred (Swanepoel 1995). In India, Ganjam virus was isolated from ticks collected from sheep and goats in Orissa state (Karabatsos 1985). Ganjam virus is now considered to be synonymous with Nairobi sheep disease virus (Davies et al. 1978). Dugbe virus, another virus of the genus *Nairovirus*, has been isolated many times from cattle ticks in Nigeria (Kemp et al. 1971), and there have been a few Dugbe virus isolations from febrile humans.

Rift Valley fever virus

Epizootics of Rift Valley fever virus were first reported at the beginning of the twentieth century, but the virus was first isolated in the 1930s in the Rift Valley of Kenya, where sheep suffered fatal hepatic necrosis and abortion. Since then, there have been many epizootics throughout subSaharan Africa, and associated human disease has been described. In 1977, Rift Valley fever was first documented outside subSaharan Africa, when an outbreak occurred in Egypt (Hoogstraal 1979; Laughlin et al. 1979; Meegan 1979). Extensive human and animal disease occurred in Egypt, including the Nile delta region, between 1977 and 1979, but adjacent countries were spared. Transmission appears to have ceased in 1979. In 1993, however, Rift Valley fever once again appeared in Egypt, initially in Upper Egypt near Aswan, and subsequently in the Nile delta (WHO 1994). This presumed importation has likewise not spread beyond Egypt's borders, and may have been contained or eliminated by an aggressive vaccination campaign.

The disease appeared in Mauritania and Senegal in 1987 when an estimated 224 patients died in Mauritania, and many abortions occurred in sheep and goats. This epidemic was associated with flooding at the Diama Dam near the mouth of the Senegal River (Digoutte and Peters 1989). In 2000, the virus was detected in Yemen and Saudi Arabia where nearly 2 000 cases were reported with an estimated 245 deaths. Genetic studies of the virus were consistent with the theory that infection was introduced from East Africa (Shoemaker et al. 2002).

Sheep, cattle, and goats suffer 10–30 percent mortality from Rift Valley fever virus, and a large percentage of infected pregnant animals abort. Disease and death are most frequent in young animals. Native ungulates seem to be more resistant to lethal infection. Disease in humans is characterized by acute onset of fever, headache and myalgia with incapacitating prostration. The incubation period is typically 2–6 days; in most patients the illness resolves after 2–3 days' rest, although symptoms may persist for a week. A small proportion, perhaps 1 percent, of cases develop hemorrhagic fever, encephalitis, or retinal vasculitis. Hemorrhagic disease begins as typical Rift Valley fever, but patients develop gastrointestinal bleeding, become jaundiced, and may die in shock. Disseminated vascular damage and hepatic failure may contribute to the cause of death. Fatal encephalitis may also follow Rift Valley fever, which typically develops a few days to 1–2 weeks after initial recovery from classic disease. Patients develop

headache, confusion, return of fever, and various neurological signs that may lead to residual illness or death. Similarly, ocular complications appear up to 3 weeks after acute disease, presenting with rapid onset of decreased visual acuity due to retinal hemorrhage, exudates, and macular edema. Vision returns as the edema and exudates resolve, but about half the patients suffer some degree of permanent visual loss.

Sandfly fever and related viruses

Sandfly fever, also known as pappataci fever or phlebotomus fever, has been recognized as a militarily important disease since the Napoleonic Wars (Hertig and Sabin 1964). During both World Wars, foreign troops suffered significant incidence rates of sandfly fever in the Mediterranean theaters. These viruses are transmitted by the bite of infectious sandflies (genus *Phlebotomus*, thus 'phlebotomus fever'), and take their names from the sites of their original isolation. Sabin was the first to demonstrate that these two distinct viruses could cause virtually identical diseases in humans (Sabin 1951). The clinical syndrome after infections with either Naples virus or Sicilian virus is characterized by abrupt onset of fever lasting 2–4 days, headache, eye pain, photophobia, pain in the back and joints, anorexia, and malaise. Nausea and vomiting, other abdominal symptoms, sore throat, drowsiness, dizziness, and saddleback fever may also be seen, but rash or meningeal signs are uncommon (Sabin 1951; Hertig and Sabin 1964; Bartelloni and Tesh 1976). No deaths have been documented among several hundred cases studied, and no sequelae are recognized. Life-long homologous protection probably follows infection, but there is no crossprotection between Naples and Sicilian viruses.

Toscana virus was isolated in 1971 from sandflies (*Phlebotomus pernicious*) captured in the Tuscany region of central Italy (Verani et al. 1980). Subsequent investigations there have shown it to be the causative agent in many cases of summertime aseptic meningitis (Verani and Nicoletti 1995). Serological surveys have found antibodies to Toscana virus in other southern European countries as well, although its health impact in these areas is less well characterized (Balducci et al. 1985).

New World sandfly fever viruses

Alenquer, Candiru, Chagres, and Punta Toro are all New World sandfly fever viruses originally isolated from febrile patients. The clinical disease following infection with any of these viruses is virtually indistinguishable from that seen in Naples or Sicilian infections. Human cases are not common owing to the secretive nature of their New World sandfly vectors (genus *Lutzomyia*), which inhabit tropical forests and are unlikely to come into contact with large numbers of humans. Even so, antibody prevalence rates ranging from 2 to 34 percent for Punta Toro virus were detected in serological surveys of residents of rural Panama, and about half those rates for Chagres virus (LeDuc et al. 1980).

Other infections

Bangui virus causes a febrile illness with rash in the Central African Republic. It has also been recovered from a bird in the same country (Digoutte et al. 1980).

Bhanja virus was first isolated in India from *Haemaphysalis intermedia* ticks collected from goats in Ganjam district, Orissa (Shah and Work 1969). Other isolations have been made from cattle and goat ticks in West Africa, and from blood samples collected there from cattle, sheep, ground squirrels, and hedgehogs. Bhanja infection of goats is widespread in the former Czechoslovakia, Italy, and the former Yugoslavia; and many animal sera collected in Sri Lanka have antibodies against this virus. Infection of humans caused severe neurological disease and death in at least two cases in the former Yugoslavia, and laboratory infections have occurred (Vesenjak-Hirjan et al. 1980).

Bwamba virus was first isolated from acutely ill febrile patients in Bwamba County, Uganda (Smithburn et al. 1941). Later serological studies have found high prevalence rates of antibodies to this and closely related viruses throughout East, Central, West, and South Africa. Bwamba virus seems to be a common cause of febrile illness in humans in Africa, causing a self-limiting disease accompanied by rash and prostration, often with meningeal signs (Georges et al. 1980). Bwamba and a closely related virus, Pongola, have been isolated from various mosquito species, but little is known about their natural history. Kasokero virus has been isolated from bats in Uganda, where it may cause fever in humans (Kaluda et al. 1986). Laboratory infections have occurred.

Cache Valley virus has been associated with congenital malformations in sheep and cattle, and serological surveys have frequently found antibodies in domestic animals and humans throughout the Americas. Human disease is uncommon. However, a recent report of severe encephalitis and multiorgan failure attests to its ability to cause life-threatening illness (Edwards et al. 1989; Sexton et al. 1997).

Garissa virus is a reassortant bunyavirus. It was isolated from acute hemorrhagic fever cases during an epidemic of Rift Valley fever in Kenya and southern Somalia in 1997 and early 1998. Initial studies indicated that the sequences of the L and S RNA segments were nearly identical to those of Bunyamwera virus, whereas the sequence of the M segment was very different (33 percent nucleotide and 28 percent amino acid differences from Bunyamwera virus). Acute sera of 14 hemorrhagic fever cases yielded either virus isolation or PCR evidence of infection (Bowen et al. 2001). Very recent

studies have shown that Garissa and Ngari virus M segments are nearly identical in sequence while the L and S segments of Bunyamwera virus are very similar to Ngari virus. These data indicate that Garissa virus is not a reassortant but is an isolate of Ngari virus, which is a reassortant of Bunyamwera virus (Gerrard et al. 2004). Previously, Ngari virus has not been considered a cause of hemorrhagic fever and further studies are required to investigate the pathogenesis and epidemiology of Ngari virus.

Keterah virus, isolated in Malaysia from Argas ticks and from bats, is indistinguishable from Issyk–kul virus, which has been isolated from *Aedes caspius* mosquitoes and from bats (*Nyctalus noctula*, *Myotis blythii* and *Vespertilio serotinus*) and ticks (*Argasvespertilionsis*) in Kirghiz SSR, the former USSR. It has since been associated with epidemics of febrile disease in humans in that region (Lvov et al. 1984).

Nyando virus was isolated from mosquitoes in Kenya, and from humans in the Central African Republic, where it caused fever, myalgia, and vomiting (Digoutte et al. 1980).

Tamdy virus is a tick-borne virus causing a febrile illness in humans in the Asiatic regions of the former USSR (Lvov et al. 1976).

Tataguine virus is a mosquito-borne virus that causes fever, joint pains, and rash in humans in Africa (Digoutte et al. 1980).

Wanowrie virus was isolated from *Hyalomma marginatum isaaci* ticks collected from sheep in India, and from the brain of a 17-year-old girl who died in Sri Lanka after a 2-day fever with abdominal pain and vomiting (Pavri et al. 1976). The virus is also present in Egypt and Iran (Sureau and Klein 1980).

Epidemiology

GENERAL CONSIDERATIONS

Viruses of the family *Bunyaviridae* are maintained in nature in a complex life cycle, usually involving an arthropod vector and a vertebrate host. The exceptions are viruses of the genus *Hantavirus*, which are maintained by chronic infection of rodents and other small mammals. In general, each virus is specifically associated with a particular arthropod species that serves to transmit the virus, and one or more species of vertebrate hosts that serve to amplify the virus following infection through a transient viremia. Arthropod vectors, especially mosquitoes, are often seasonally abundant, which results in seasonal transmission of the viruses they transmit. During periods of adverse weather conditions, virus survival is often maintained by vertical or transovarial transmission whereby an infected female passes the viral infection on to the next generation of vectors. The virus survives in association with the dormant egg and, with hatching and subsequent development, virus transmission to vertebrate hosts takes place during blood feeding. Viruses may also be transmitted venereally from infected males to uninfected female vectors during mating. Vertebrate hosts serve to amplify the amount of virus in circulation by means of a viremia of varying intensity and duration. Uninfected vector species become infected when ingesting a viremic bloodmeal. Following an extrinsic incubation period of a few days' duration, during which the virus replicates and is disseminated throughout the vector, the newly infected vectors are then able to transmit the virus at subsequent blood feeding. Mosquitoes are the most important group of arthropod vectors, but ticks, sandflies, and biting midges (*Culicoides* spp.) are also important vectors for certain viruses.

Most of the bunyaviruses are zoonotic in nature, and humans are usually only accidental hosts that generally do not facilitate amplification of the virus in nature. Exceptions are Oropouche virus and perhaps sandfly fever viruses, in which humans seem to be important sources of virus for uninfected vectors. Selected examples of the transmission cycles of representative viruses are presented below to demonstrate their complexity.

IMPORTANT INFECTIONS

California encephalitis due to La Crosse virus

Most viruses of the genus *Bunyavirus* are transmitted by mosquitoes, and California encephalitis due to La Crosse virus may serve as an example of one of the better understood transmission cycles (see Calisher and Thompson 1983, for overview). The mosquito *Aedes triseriatus* is the principal vector of La Crosse virus. This species is common in the hardwood forests of the upper midwestern United States, where it breeds primarily in tree holes. It survives the harsh winters in the egg stage. In late spring or early summer the first adults emerge, mate, and begin to seek a blood meal. La Crosse virus is transmitted transovarially from infected adult female *Ae. triseriatus* to the next generation of eggs, so a proportion of those newly emerging adults are already infected with the virus (Watts et al. 1973, 1974). These infected females transmit the virus to susceptible vertebrate hosts at blood feeding, beginning the amplification cycle each year, whereas infected males may pass the virus to uninfected females during mating. (Male mosquitoes do not feed on blood, and thus cannot transmit the virus directly to an amplifying vertebrate host.) *Ae. triseriatus* females typically feed during the day, most frequently on squirrels, chipmunks, foxes, and rabbits, and on humans if present. Susceptible squirrels and chipmunks circulate the virus in high enough titer to infect other *Ae. triseriatus*, thus serving to amplify the prevalence of virus in the vector population. Foxes, with their larger range, may both amplify the virus among local vector populations and also disseminate it to more distant vector populations (Yuill 1983). Humans are infected

when they enter the woods for recreation or work, most clinical cases being seen among children less than 15 years old. As *Ae. triseriatus* breeds equally well in discarded tyres or other items that retain water, infected mosquito populations may flourish in close proximity to dwellings, increasing the risk of infection to residents. Prevention of California encephalitis due to La Crosse virus can be facilitated by clean-up campaigns to reduce the availability of mosquito breeding sites, but elimination of all breeding is probably impossible owing to the abundance of natural breeding sites (Francy 1983).

Oropouche virus

Although most viruses of the genus *Orthobunyavirus* are transmitted by mosquitoes, some, such as Oropouche and other members of the *Simbu* serogroup, are transmitted by biting midges (family *Ceratopogonidae*, genus *Culicoides*). Oropouche virus was first described from Trinidad, but in the past two decades has become a major public health problem in northern Brazil and adjacent Amazon Basin nations (for an overview, see LeDuc and Pinheiro 1988). This increase is almost certainly a result of the changing ecology of the Amazon Basin, deforestation leading to human settlements and large plantations of banana and cacao, with the organic waste from these and other crops serving as ideal breeding sites for the vector *Culicoides*. This has led to tremendous population densities of *C. paraensis* in many parts of the Amazon Basin. Oropouche virus is thought to be maintained in two distinct transmission cycles: silent sylvatic transmission involving nonhuman primates, sloths, and perhaps other vertebrate hosts, and an urban cycle in which humans are the primary amplifying and disseminating host and *C. paraensis* serving as the primary vector (Pinheiro et al. 1981). This species lives in close association with humans and readily feeds during daylight hours. Epidemics occur when midge populations are large, the majority of the human population is susceptible and Oropouche virus is introduced from the silent sylvatic cycle into the urban setting. Although only a small percentage of the midges are able to transmit the virus, it seems that the populations are often so abundant that transmission is sustained until the majority of those humans susceptible have been infected. Humans circulate virus in sufficiently high titers to infect feeding *C. paraensis*, and consequently may serve to introduce the virus to new areas through their travel. With the increasing deforestation of the Amazon Basin, epidemics of Oropouche and other previously uncommon viruses found there are likely to increase.

Hantaan and related hantaviruses

Unlike other viruses of the family *Bunyaviridae*, arthropod vectors do not seem to play a significant role in the transmission of the hantaviruses. It seems that the hantaviruses, perhaps like other members of the family, represent an excellent example of co-evolution of the virus with a specific vertebrate host. As information about each of the genetically unique hantaviruses accumulates, it is increasingly apparent that each virus is specifically linked to a particular species of rodent host. These associations are shown in Table 2. The virus lineages closely follow the origin of the rodent hosts. Within the rodent family *Muridae*, three subfamilies exist: *Murinae*, *Arvicolinae*, and *Sigmodontinae*; the hantaviruses maintained by rodent species of each of these subfamilies are genetically most closely related to each other, and less so to those of viruses associated with rodents of the other subfamilies (see Figure 5) (for an overview, see LeDuc 1995). Transmission of hantaviruses between rodent hosts is thought to occur by aerosol from infectious excreta, and perhaps by saliva (Glass et al. 1988; Nuzum et al. 1988). Biting may play an important role in transmission of hantaviruses among rodents as territories are set and mating occurs (Glass et al. 1988). Studies have failed to demonstrate direct transmission from infected parent rodents to their offspring. Humans are infected when they come into contact with infected rodent hosts. There is thus a strong occupational association with the risk of hantaviral infection, farmers, woodcutters, soldiers, and others with significant rural exposure being most often infected. Hantaviral infections are seasonal. They occur frequently in warmer months when recreational activities and outdoor work bring people into close contact with infected rodents. Infections caused by hantaan and Puumala virus peak in prevalence also in late fall and early winter in Asia and Europe, respectively. In cold seasons, the rodents seek shelter in homes and sheds, infecting not only male workers, but also children and women.

Crimean–Congo hemorrhagic fever virus

Crimean–Congo hemorrhagic fever (CCHF) virus serves as an excellent example of two aspects of the epidemiology of viruses in the family *Bunyaviridae*: the threat of nosocomial or other direct transmission from infected blood to susceptible humans, and transmission by ticks (for overviews, see Hoogstraal 1979; Watts et al. 1989; Swanepoel 1995). CCHF virus is widely distributed from eastern Europe to Asia and Africa. In general, its distribution follows closely that of the primary tick vectors of the genus *Hyalomma*. Immature ticks acquire infection during feeding on viremic hosts, often small mammals, or by vertical transmission from infected females to the progeny. As ticks develop, the virus may be transmitted transstadially to subsequent developmental stages, and infected ticks may pass the virus to uninfected females during mating. Adult females, including those infected venereally, may then pass the virus to subsequent generations transovarially (Gonzalez et al. 1992). Viremia occurs after infection of small mammals as well

as of domestic ruminants, which may serve to infect uninfected tick vectors. The proportion of uninfected ticks that becomes infected when feeding on a viremic host generally increases with the intensity of viremia. In addition, nonviremic transmission, as described for Dugbe virus, is also thought to occur with CCHF (Jones et al. 1987; Jones et al. 1989).

Humans become infected either through the bite of an infected tick or through direct contact with infectious blood from an infected animal. The original outbreak of CCHF, described from the Crimean peninsula in 1944–1946, involved large numbers of people exposed to ticks during post-war conditions, clearing agricultural lands that had been fallow. Today, however, most cases are seen among individuals in Bulgaria, Albania, and adjacent parts of the former Yugoslavia, sporadically in the Middle East, and as isolated cases in Africa, especially in South Africa where the virus is well known and studied. Clusters of cases occur in hospitals, especially in remote or ill-equipped clinics and surgeries, where the disease may not be recognized initially, and staff are infected by direct contact with infectious bodily fluids. Transmission of CCHF virus to workers in the laboratory setting has also occurred, leading to severe disease and fatalities.

Pathogenesis, pathology, and immune response

Human infection with a bunyavirus generally follows the bite of an infectious vector or, less frequently, inhalation of infectious virus. After an incubation period, a brief viremia often occurs, which corresponds to the period of acute illness. Signs and symptoms probably result from direct effects of virus on target organs, such as the liver or brain. Immunohistochemical analysis has found widespread hantaviral antigens in endothelial cells of the microvasculature of hantavirus pulmonary syndrome patients, which may reflect similar targets of infection with other hantaviruses (Zaki et al. 1995). Disseminated intravascular coagulopathy may occur in severe disease with hemorrhagic manifestations such as HFRS, CCHF or Rift Valley fever. A typical humoral immune response leads to cessation of viremia and clinical recovery in most cases, with immunoglobulin M (IgM) predominating initially, followed by immunoglobulin G (IgG). The cellular immune response to bunyavirus infections is not well defined, nor is the role of cytokines. A brief discussion of the pathogenesis, pathology, and immune response of selected diseases is presented in Clinical manifestations.

Diagnosis

Diagnosis is based on demonstration of the specific virus causing infection, by isolation, by detection of viral antigen or nucleic acids, or by acquisition of antibody specific for the infecting virus. Classic virus isolation techniques such as inoculation of suckling mice or cell cultures of mammalian or insect origin have been often used with considerable success. Likewise, routine serological techniques such as hemagglutination inhibition, complement fixation, immunofluorescent antibody assays, neutralization tests in mice or cell culture have been used to demonstrate rising or falling titers of antibody in paired sera from patients. These techniques are generally time consuming and expensive, and do not offer a definitive diagnosis soon enough to influence clinical management. Recently, more rapid diagnostic procedures have been developed that can offer a presumptive diagnosis within a few hours of receipt of a single acute serum sample. With enzyme immunoassays, viral antigen may be detected directly, or virus-specific IgM antibody demonstrated, generally in time to influence clinical management. For example, patients with HFRS due to hantaan virus are often positive for IgM antibodies at the time of hospital admission (LeDuc et al. 1990). Confirmation of the specific etiology helps in forecasting the course of the illness and initiating antiviral therapy such as ribavirin, which is efficacious in the treatment of HFRS (Huggins et al. 1991). Direct detection of viral nucleic acid, most often through reverse transcriptase-polymerase chain reaction amplification, and subsequent sequencing or endonuclease digestion of amplified products, has recently been applied for diagnosis, especially of hantavirus infections (Nichol et al. 1993). Acute specimens and autopsy tissues have both been used successfully to establish the diagnosis. However, the value of the technique is limited by the need for specially designed primers and very careful laboratory techniques to minimize the risk of contamination (Grankvist et al. 1992; Feldmann et al. 1993; Nichol et al. 1993). At present, these techniques are limited to research or reference laboratories and not widely available.

Prevention and control

Diseases caused by bunyaviruses have, with few exceptions, a low incidence of human infection and thus do not justify development of vaccines. An exception is HFRS, especially that due to hantaan virus in Asia, where several candidate vaccines are in development, under field trials or, in at least one case, commercially available (Lee et al. 1990; Schmaljohn et al. 1994). Most current candidates are inactivated whole virus vaccines that require multiple inoculations and boosters to ensure protection. However, recombinant candidates are also under development. In particular, DNA vaccines appear to have significant promise for Hantaan and related viruses (Hooper et al. 2001a; Custer et al. 2003). Development of live-attenuated vaccines for hantavirus

infections has been hampered by the absence of a suitable animal model that would faithfully mimic human disease (WHO 1995), although recent studies suggest some animal models may have utility (Hooper et al. 2001b; Milazzo and Eyzaguirre 2002; Fisher and Tesch 2003). Vaccines for Rift Valley fever virus have also been developed, with both inactivated and live attenuated products available for veterinary use, and an inactivated vaccine available on a limited basis for humans (Smithburn 1949; Eddy et al. 1981; Kark et al. 1982; Morrill et al. 1987, 1991). A live-attenuated candidate vaccine for humans is now in early clinical trails. Observational studies indicate that ribavirin has a beneficial effect in CCHF infections. Thus it may be that oral prophylactic treatment of exposed persons is warranted (Mardani et al. 2003).

Most often, however, prevention and control of bunyaviruses are based on avoidance of human contact with infected arthropod or small mammal vectors. Infection usually occurs when people enter into the ecological setting where viruses are being transmitted silently among infected vectors and wild vertebrate hosts. In these situations, personal protective measures, such as the liberal use of insect repellants and wearing appropriate clothing, may reduce the risk of infection. Likewise, care should be taken to ensure that houses, vacation cabins, or campsites do not attract or support breeding potential vectors. Thus, using screens on windows and doors and removing potential mosquito breeding sites, such as used tyres or other water-holding containers, will help prevent infections. In the case of rodentborne hantaviruses, special precautions are needed to rodent-proof homes and to maintain clean campsites.

ACKNOWLEDGMENTS

This chapter was written shortly before the death of Bob Shope. Bob's friendship and knowledge is greatly missed by all of us who work on arboviruses.

PROPERTIES OF THE ARENAVIRUSES

INTRODUCTION

The arenaviruses are enveloped, single-stranded RNA viruses that are primarily carried by rodents and occasionally transmitted to humans. Old World and New World arenaviruses have been isolated on the African and American continents respectively (see Table 1).

The arenaviruses are important clinically as human pathogens and experimentally as models for persistent infection and cellular immune responses. The prototype virus, lymphocytic choriomeningitis virus (LCMV), was first isolated from a human diagnosed with St. Louis encephalitis; tissue homogenates passaged through monkeys and mice caused fever and aseptic meningitis (Armstrong and Lillie 1934). A year later, a filterable agent was isolated from the cerebrospinal fluids of two patients; this agent elicited similar symptoms in mice (Rivers and Scott 1935). At the same time, Traub (1935) discovered a contaminant virus in the mouse colony of the Rockefeller Laboratories. Viruses were exchanged between the three laboratories and their identity was confirmed by neutralization in vitro and cross-protection in vivo (Rivers and Scott 1936). LCMV has frequently been found as a contaminant of laboratory mice, rats, and hamsters in North America and Europe, and may have entered North America via mice from Europe. Studies of murine LCMV infection have contributed to a wealth of information on the mechanisms of viral persistence and the interactions of viruses with host immune systems (see section entitled Immune response).

In 1956, the nonpathogenic Tacaribe virus was isolated from Caribbean fruit bats (Downs et al. 1963). With the agricultural expansion in South America, two pathogenic arenaviruses emerged: Junin, isolated from humans with Argentine hemorrhagic fever (Parodi et al. 1958); and Machupo, isolated from humans with Bolivian hemorrhagic fever (Johnson et al. 1965). Collaboration between field workers, the Yale Arbovirus Laboratories and the Rockefeller Laboratories documented the morphology and antigenicity of the 'Tacaribe group' of viruses. A nonpathogenic member of this group, Pichinde virus, was isolated during a trapping programme in Colombia, and has since served in many biochemical studies (Trapido and Sanmartin 1971; Cosgriff et al. 1987; Liu et al. 1986; Qian et al. 1991). More recently, other arenaviruses have been discovered in Argentina (Oliveros virus, Bowen et al. 1996), Brazil (Cupixi, Charrel et al. 2002), Venezuela (Pirital virus, Charrel et al. 2001a), Peru (Allpahuayo virus, Moncayo et al. 2001) and the US (Whitewater Arroyo virus, Charrel et al. 2001b; Bear Canyon virus, Fulhorst et al. 2002).

Table 1 Arenaviridae*: carriers and geographical distribution (modified from Clegg 2002)*

Virus	Virus carrier	Geographical distribution	Potential for human disease
New World			
Allpahuayo	*Oecomys* spp.	Peru	None reported
Amapari	*Oryzomys goeldii*	Brazil	None reported
	Neacomys guinae	Brazil	
Bear Canyon	*Peromyscus californicus*	California, USA	None confirmed
Cupixi	*Oryzomys* spp.	Brazil	None reported
Flexal	*Neacomys* spp.	Brazil	None reported
Guanarito	*Oryzomys* spp.	Venezuela	Severe
Junin	*Calomys laucha*	Argentina	Severe
	Calomys musculinus	Argentina	
	Akodon azarae	Argentina	
Latino	*Calomys callosus*	Bolivia	None reported
Machupo	*Calomys callosus*	Bolivia	Severe
Oliveros	*Bolomys obscures*	Argentina	None reported
Parana	*Oryzomys buccinatus*	Paraguay	None reported
Pichinde	*Oryzomys albigularis*	Colombia	None
	Thomasomys fuscatus	Colombia	
Pirital	*Sigmodon alstoni*	Venezuela	None reported
Sabía	Not known	Brazil	Severe
Tacaribe	*Artibeus literatus*	Trinidad	None reported
	Artibeus jamaicensis	Trinidad	
Tamiami	*Sigmodon hispidus*	Florida, USA	None reported
Whitewater Arroyo	*Neotoma* spp.: *albigula*, *cinerea*, *mexicana*, *micropus*	New Mexico, USA	Three fatalities had a virus, 87 percent identical to WWA
Old World			
LCM	*Mus musculus*	Worldwide	Mild to severe
Lassa	*Mastomys natalensis*	West Africa	Severe, often fatal
Mopeia	*Mastomys natalensis*	Mozambique Zimbabwe	None reported
Mobala	*Praomys jacksoni*	Central African Republic	None reported
Ippy	*Mastomys natalensis*	Central African Republic	None reported

It was not until the late 1960s that the morphological similarities between LCMV and the Tacaribe group of viruses were noted: both were enveloped viruses with a granular or sandy appearance. Serological tests later confirmed the relationship and they were named arenaviruses after the Latin *arena* for 'sandy' (Johnson et al. 1965; Dalton et al. 1968; Rowe et al. 1970). When Lassa fever virus emerged in Africa, it was quickly identified as an arenavirus on morphological and serological criteria (Murphy 1975). Arenaviruses are considered 'emerging pathogens' because new isolates are coming to our attention with great frequency (Coimbra and Nassar 1994). The following publications contain more details about the arenaviruses: Oldstone (2002); Bishop (1990); McCormick (1990); Salvato (1993a); Southern (1996); Buchmeier et al. (2001), and Peters (1997).

CLASSIFICATION

The *Arenaviridae* are one of seven families of negative-strand RNA viruses, the others being *Filoviridae, Rhabdoviridae, Paramyxoviridae, Orthomyxoviridae*, *Bunyaviridae*, and *Bornaviridae*. These viruses are characterized by single-stranded, non-infectious genomic RNA that requires a virus-encoded RNA transcriptase to initiate replication. Arenaviruses have been classified by a combination of morphological characteristics, biochemical analyses, and immunological tests (Pfau 1974) and are the only family of negative-strand RNA viruses with a bisegmented genome (Pedersen 1979). Under the Old World and New World groupings are at least 22 species of arenaviruses (Table 1) with the probable addition of further viruses as surveillance continues. Genetic relationships among the arenaviruses can be depicted by a phylogenetic tree based on the sequence differences between viral nucleocapsid proteins (Figure 1). A recent comparison (Bowen et al. 2000) found the broadest range of sequences within the *Lassa* species, i.e. up to 24.1 percent nucleotide divergence and up to 12 percent amino acid divergence. However, two distinct species of New World arenaviruses, *Junin virus* and *Machupo virus*, were relatively similar to each other with 23.3 percent nucleotide divergence and 13.7 percent amino acid divergence.

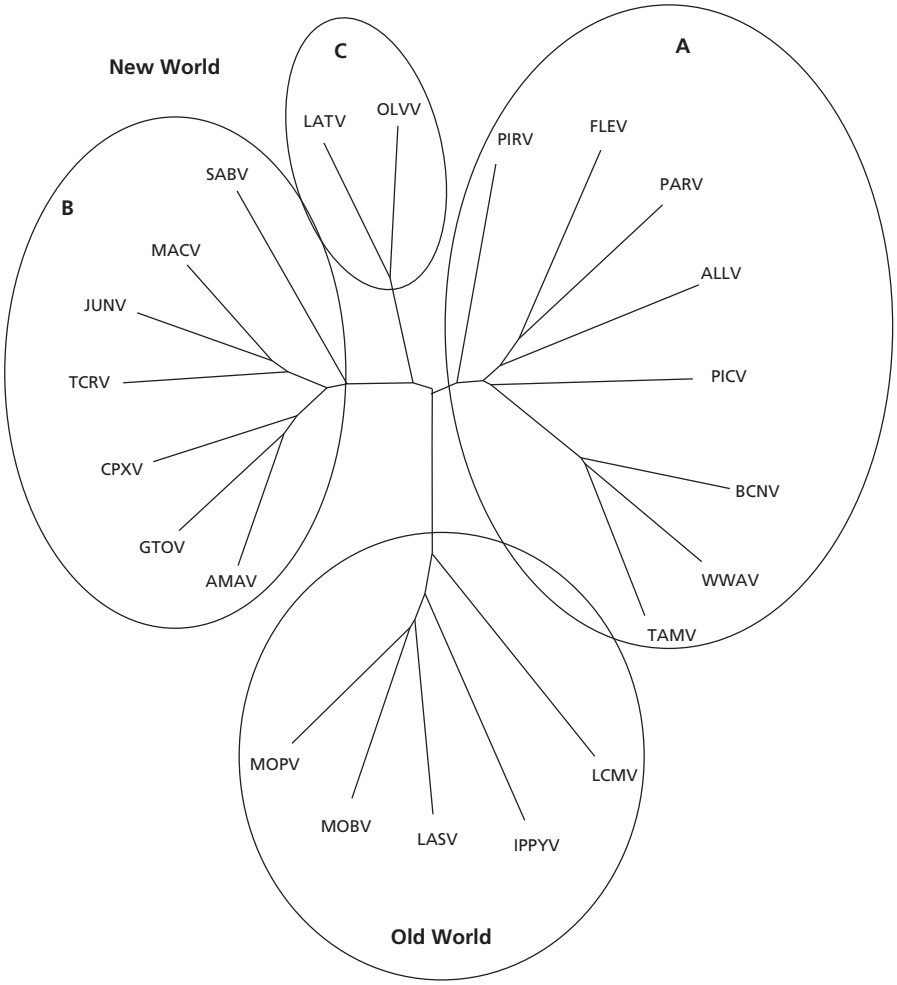

Figure 1 *Phylogenetic relationships among the* Arenaviridae. *Partial* N *gene nucleotide sequences corresponding to nt 1770–2418 of* Tacaribe virus *S RNA sequence (GenBank accession no. M20304) were aligned (Clustal X 1.81) and analyzed by Jukes–Cantor algorithm and neighbor-joining method using the MEGA v2.1 software program (modified from Bowen et al. 2000).*

Considering that picornaviruses have as much as 30 percent amino acid divergence within species (Dahourou et al. 2002), the arenaviruses are considerably subdivided. In addition to sequence criteria, classification of arenaviruses is influenced by the ability of viruses to reassort with one another, i.e. intraspecies reassortment should be possible and interspecies reassortment, as between *Lassa virus* and *Mopeia virus* (Lukashevich 1992), is rare.

DISTRIBUTION

The worldwide distribution of arenaviruses follows the distribution of their natural reservoir hosts, primarily rodents (Figure 2). Occasionally, infected humans have traveled extensively, resulting in movement of the viruses (Holmes et al. 1990).

Although there are over 30 families of rodents, the arenaviruses are associated with only two major families: the *Muridae* (e.g. house mice and rats) and the *Cricetidae* (e.g. voles, deer mice, and gerbils). The *Muridae* inhabit human dwellings and food stores, in contrast to the *Cricetidae* that live in the open grasslands. Muridae include *Mastomys*, that carries the Lassa-like viruses; *Praomys*, that carries Mobala; and *Mus*, that spread from the Old World to the rest of the globe, simultaneously dispersing LCMV. The cottonrat, *Sigmodon hispidus*, from which Tamiami virus was isolated in the USA, is related to the *Cricetidae*: *Calomys, Akadon, Oryzomys*, and *Neocomys* of South America and *Peromyscus* of North America. Tacaribe virus is an exception in that it was isolated from the fruit bat, *Artibeus*. It is notable that infections follow seasonal associations between humans and carriers; for example, the harvest season in Argentina, April to June, is also the peak time for the occurrence of Argentine hemorrhagic fever.

MORPHOLOGY AND STRUCTURE

The envelope composition of an arenavirus derives from host-cell membranes during maturation from the cell

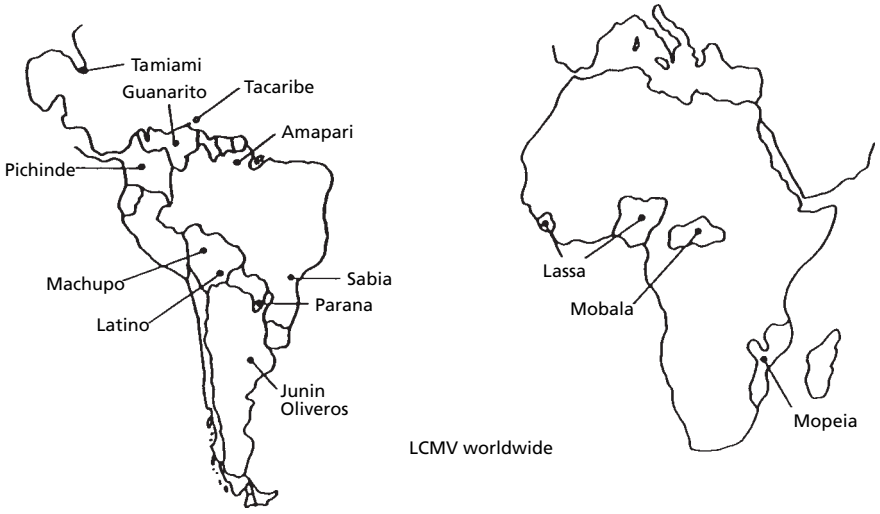

Figure 2 *Map of the distribution of Old World and New World arenaviruses. The Old World viruses originated on the European and African continents and the New World viruses originated in the Americas.*

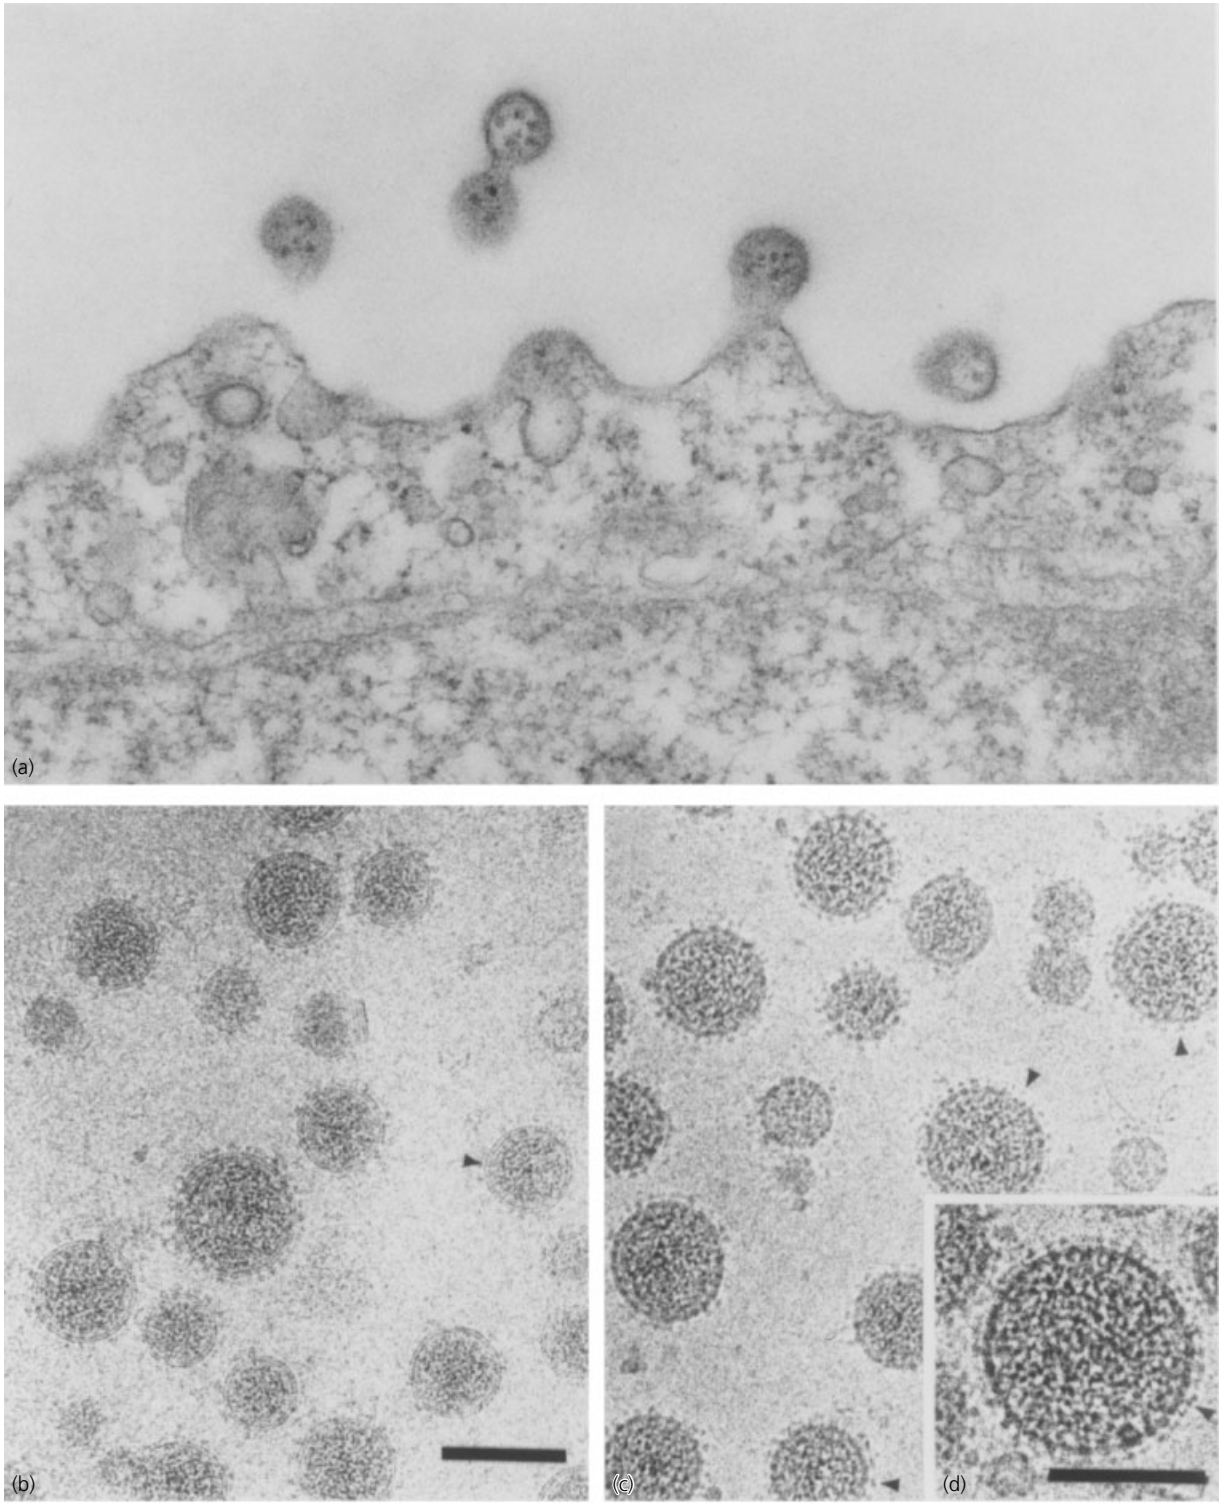
surface (Figure 3a). The envelope is sensitive to organic solvents and detergents; treatment with these reagents can be used to separate viral cores from their envelopes. Virions are also sensitive to UV and gamma-irradiation, to heating at 56°C, and to pH outside the range of 5.5–8.5. Acid or high salt treatment of LCMV causes one of the envelope glycoprotein chains, GP-1, to dissociate from the virion surface, whereas the other chain, GP-2, remains anchored in the envelope (Di Simone et al. 1994). Acid treatment of LCMV decreases its Vero cell infectivity, which is due to virus aggregation or the loss of GP-1. Virions are generally purified from the media surrounding infected cells by a combination of precipitation with 7 percent polyethylene glycol and centrifugation: buoyant densities are 1.9–1.2 g/cm^3 in cesium chloride, 1.17–1.18 g/cm^3 in sucrose and 1.14 g/cm^3 in amidotrizoate (Buchmeier et al. 1978).

Originally, electron micrographs showed arenaviruses as highly pleiomorphic, probably because of their instability during fixation procedures. More recently, cryo-electron micrographs have revealed spherical particles with an average diameter of 90–110 nm (Burns and Buchmeier 1993) (Figure 3c, d). Glycoproteins on the surface of the virion form T-shaped spikes extending 7–10 nm from the envelope. Electron-dense granules within arenaviruses, from which the name 'arena' derives, are ribonucleoprotein particles. These include ribosomal RNA, and perhaps whole ribosomes, and more of such particles are present in late viral harvests than in early harvests (Farber and Rawls 1975; Pedersen 1979; Dutko and Oldstone 1983; Southern et al. 1987). With Pichinde virus, virion-associated ribosomes are not essential for the infectious process; viruses produced in cells containing *ts* ribosomes are infectious even at the nonpermissive temperature (Leung and Rawls 1977). Electron microscopy of disrupted virions reveals circularized strings of ribonucleoproteins (Palmer et al. 1977) that may have resulted from the self-annealing of the RNA termini that encode approximately 20 bases of complementary nucleotides.

Arenaviruses produce defective interfering (DI) particles (reviewed by Buchmeier et al. 1980a). DI particles are generated rapidly during infection of tissue cultures with LCMV, and render the cells resistant to superinfection with LCMV, less resistant to Pichinde and entirely susceptible to heterologous viruses (Lehmann-Grube et al. 1969; Welsh and Buchmeier 1979). DI particles sediment to a lower density than infectious virus and have a smaller target size for UV inactivation, and their concentration can be measured by cytopathogenicity-reduction assays. DI particles of Pichinde lack conventional S RNA (Dutko et al. 1976).

GENOME STRUCTURE AND FUNCTION

The arenaviruses contain single-stranded RNA that consists of 2 RNA segments, L ca. 7000 bases and S ca. 3400 bases. Complete sequences are now available for LCMV, Lassa, Tacaribe, and Pichinde, and partial sequences for Junin, Mopeia, and other arenaviruses (Romanowski et al. 1985; Auperin et al. 1986; Auperin and McCormick 1989; Iapalucci et al. 1989; Salvato and Shimomaye 1989; Salvato et al. 1989; Ghiringhelli et al. 1991; Harnish et al. unpublished; reviewed in Clegg 1993). Four open reading frames have been identified: a gene for the envelope glycoprotein is encoded at the 5′ end of the S RNA segment, and, in the negative sense, a gene for the nucleocapsid protein is encoded at the 3′ end of the S RNA. A gene for a small zinc-binding protein is encoded at the 5′ end of the L RNA, and, in the negative sense, a gene for the viral RNA polymerase is encoded at the 3′ end of the L RNA (Figure 4).



Figur 3 *Electron micrographs of LCM virions.* **(a)** *Thin section showing virions budding from infected BHK-21 cells. Typical 110 nm virions containing 20 nm electron-dense particles are evident.* **(b)** *Cryo-electron micrograph of unstained LCM virions at the 1.5 μm defocus level to emphasize lipid bilayer (see arrow) and in* **(c)** *cryo-electron micrograph of LCM at the 3 μm defocus level to emphasize surface topography. Figure 4 *The two arenavirus RNA segments, L and S, are depicted with the four encoded genes: Z (zinc-binding protein), L (polymerase), GP (envelope glycoprotein) and NP (nucleocapsid protein). (Reproduced from Salvato 1993b)*

A hallmark of the arenaviruses is their 'ambisense' coding strategy (Auperin et al. 1984). Each RNA segment encodes a gene in the positive (mRNA) sense and an additional nonoverlapping gene in the negative sense, i.e. the latter gene must first be transcribed to obtain the mRNA sense. The viruses are classified as negative strand, because the mRNA sense genes cannot function in translation directly from the genomic RNA; subgenomic mRNA copies of these genes must first be produced by transcription (Figure 5).

Strong secondary structures can be predicted for arenavirus genomic RNAs: stem–loops in the intergenic regions and base-paired 'panhandles' at the termini of the RNA segments. The terminal 20 bases of the arenavirus genomic RNA are conserved between genera and are almost identical within one arenavirus strain. It is possible to form intra- and extramolecular complexes, i.e. the 3′ and 5′ termini of the S RNA can anneal with each other or the 3′ of the S RNA can anneal with the 5′ of the L RNA, and so on. It has been suggested that this conserved terminal structure may represent a binding site for the viral RNA polymerase (Salvato 1993b) (Figure 6).

Reassortment of the two genomic RNA segments has been used to map functions to one segment or the other. Production of reassortant viruses involves infection of cultured cells with two virus isolates at once and screening for progeny virus by nucleic acid hybridization, reverse transcriptase polymerase chain reaction (RT-PCR), or by limited sequence analysis. Reassortant

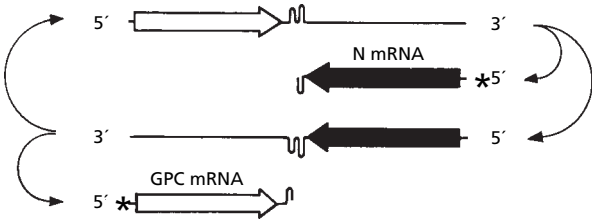

Figure 5 *The ambisense coding strategy of the arenaviruses is illustrated for the S RNA segment of* Junin virus. *First, the subgenomic nucleocapsid mRNA (N mRNA) is made and then the full-length antigenomic RNA is made (this is a 'replication intermediate'); finally, the subgenomic glycoprotein mRNA (GP-C mRNA) is made. For the L RNA a similar sequence occurs with the L and Z subgenomic mRNAs. (Reproduced from Romanowski 1993)*

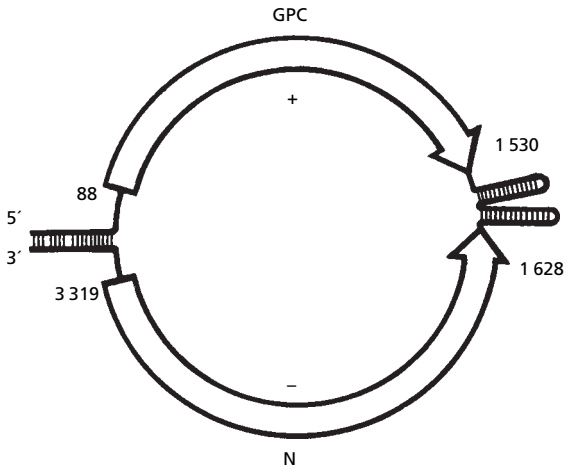

Figure 6 *The S RNA segment of* Junin virus *can be predicted to form strong secondary structures at the RNA terminus (a panhandle of the 3′ and 5′ ends) and at the intergenic region (a double stem–loop structure). The glycoprotein (GP-C) and the nucleocapsid protein (N) open reading frames are in opposite coding sense on either side of the intergenic stem–loops. (Reproduced from Romanowski 1993)*

viruses that contain the S RNA of one parental virus and the L RNA of the other can usually be isolated. This approach was used to show that the virulence of LCMV WE for guinea-pigs mapped to the L RNA (Riviere 1986), that the S RNA of LCMV Armstrong is associated both with diminished growth in C3H mice (Oldstone et al. 1985) and with the emergence of insulin-dependent diabetes in nonobese diabetic mice (Oldstone et al. 1990), and that the persistence of an LCMV Armstrong isolate depends on the L RNA (Matloubian et al. 1993). The latter case illustrates one shortcoming of this approach in that the persistent phenotype is likely to be pleiotropic, with essential genetic components on both RNAs (Salvato et al. 1991). Likewise, reassortant viruses between the Old World arenaviruses Mopeia and Lassa allowed mapping of the ability of Lassa S segment to protect against a lethal intracerebral inoculation of Lassa virus in the murine model (Lukashevich 1992).

A reverse genetics system developed by the de la Torre laboratory indicates a transcription inhibitory function for Z protein (Lee and de la Torre 2002)

REPLICATION

Tropism and virus entry

Arenaviruses replicate in a broad range of mammalian hosts and in almost every tissue of the host, reaching high titers in brain, kidney, liver, and secondary lymphoid organs (see Figure 9). Virus replication is restricted in lymphocytes, macrophages, and terminally differentiated neurons, probably because of the absence

of host cell factors (Borrow et al. 1991; de la Torre et al. 1993; Polyak et al. 1995a). Arenaviruses are often propagated in adherent cell lines such as BHK-21 cells, mouse L cells or Vero cells. The broad range of mammalian cells that can be infected suggests that the receptor for virus entry is fairly well conserved. In attempts to find the receptor for LCMV, Borrow and Oldstone (1992) used a virus overlay blot assay to identify a 160 kDa glycoprotein from rodent fibroblasts. Further studies of this protein made it clear that several arenaviruses bind to a 120–140 kDa cellular glycoprotein identified as α-dystroglycan (Cao et al. 1998). However, variations in binding affinity to α-dystroglycan were observed among the LCMV strains, with LCMV Cl –13 and WE strains being typical of high affinity binders while Arm binds at low affinity. Other arenaviruses (i.e. Lassa, Mobala, Oliveros) also bind to this glycoprotein, but Guanarito virus does not, suggesting that more than one cellular protein may serve as a receptor for arenaviruses (Buchmeier 2002).

Arenavirus entry into cultured cells is sensitive to lysosomotropic agents (Pichinde: Mifune et al. 1971; Lassa and Mopeia: Glushakova and Lukashevich 1989, Glushakova et al. 1992; LCMV: Borrow and Oldstone 1994; Di Simone et al. 1994). In the case of LCMV, this uptake was not affected by cytochalasins, so does not require clathrin-coated pits and takes place in smooth-walled vesicles by 'viropexis.' Once the virus is in the cell, the life cycle of uncoating, mRNA transcription, translation, and genome replication takes place in the cytoplasm, with some contribution from host-cell components for transcription and translation (Figure 7).

Arenavirus gene expression

The ambisense coding arrangement of the arenavirus genome provides a mechanism for temporal regulation of gene expression: NP and L mRNAs can be transcribed from the incoming genomic RNA, whereas GP and Z mRNAs are transcribed only from RNA antigenomic templates that also function as replication intermediates. Kinetic analysis of LCMV replication shows simultaneous accumulation of NP and GP mRNA (Fuller-Pace and Southern 1988), but in Tacaribe virus, newly synthesized NP mRNA accumulates before the onset of RNA replication. Furthermore, inhibition of protein synthesis during early infection prevents RNA replication but allows the continued synthesis of NP mRNA (Lopez and Franze-Fernandez 1985; Franze-Fernandez et al. 1987). For LCMV, it has been shown that the Z mRNA is included in the virion, unlike mRNAs for the other viral genes, and may be essential at an early stage of the viral life cycle (Salvato and Shimomaye 1989). Further work with inhibitors of transcription and translation will be necessary to characterize the sequence of events in arenavirus replication.

Arenavirus mRNA transcription begins with 3–7 nontemplated nucleotides: this has been demonstrated for the 5′ terminus of the NP mRNA in Tacaribe virus (Raju et al. 1990), the NP and GP mRNAs in LCMV

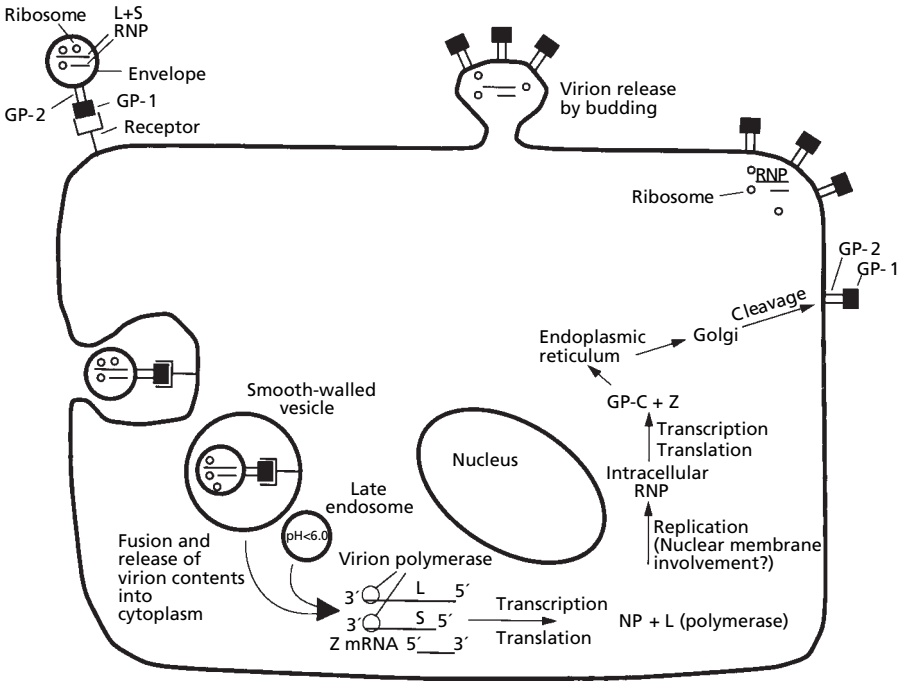

Figure 7 *Arenavirus life cycle. L, large RNA segment; S, small RNA segment; RNP, ribonucleoprotein. RNP complexes in the virion contain viral genomic RNA, Z mRNA, viral proteins, and host components such as ribosomal proteins.*

(Meyer and Southern 1993) and the NP and GP mRNAs in Pichinde virus (Polyak et al. 1995b). Genome and antigenomes generally have one nontemplated base. These may arise either by de novo synthesis or by a cap stealing mechanism as has been described for the *Orthomyxoviridae* and the *Bunyaviridae* (Garcin and Kolakofsky 1990).

The noncoding regions of arenavirus genomic RNA have the potential to form several stem–loop structures that are well placed to regulate transcription and translation. LCMV, Lassa, and Pichinde viruses each have single intergenic stem–loops on the S RNA, whereas Mopeia, Tacaribe, and Junin viruses each predict double stem–looped structures (reviewed by Clegg 1993). Translation termination codons have been described on the proximal side of the intergenic stem–loops on the S RNA and L RNA. Transcription terminations for Tacaribe virus NP, GP, Z, and L mRNAs have been described at the distal portion of each stem–loop, indicating that the secondary structure is not acting to stop transcription. Furthermore, since transcription termination has been described at multiple positions on the stem, it is likely that the polymerase is displaced from the RNA by an extragenomic factor rather than by a feature of the genome structure (Franze-Fernandez et al. 1993; Meyer and Southern 1993). Thus, since it appears that the intergenic stem–loops may help stop translation, in conjunction with the encoded stop codons, they are unlikely to serve as terminators or attenuators of transcription, and they may serve as recognition or nucleation points for virus assembly and encapsidation.

Recent studies using a LCMV RNA analogue, showed clearly that L and NP are the minimal viral factors required for efficient RNA synthesis mediated by the LCMV polymerase (Lee et al. 2000). In addition, this system allowed tests for the *cis*-elements required for transcription and replication of LCMV genome in vitro (Lee et al. 2002).

Virus–host interactions during arenavirus replication

LCMV infections in carrier mice (covered more extensively in the section entitled Clinical and pathological aspects) can persist in a broad range of tissues, without detectable cellular damage or inflammation (see Figure 9). However, some terminally differentiated cell functions or 'luxury functions' can be abolished by the presence of replicating virus. For example, a reduction of macrophage lymphokines, growth hormone, thyroid hormones, and acetylcholinesterase have been observed in persistently infected murine systems (Jacobs and Cole 1976; Oldstone et al. 1977, 1982, 1985; Rodriguez et al. 1983; Klavinskis and Oldstone 1987). The ability of LCMV to affect differentiated functions of the immune, neural, and endocrine systems depends on the genetic background of the host.

In tissue culture at low multiplicity of infection (i.e. moi <0.1) arenavirus replication is not detected for 6 h, after which cell-associated virus increases exponentially. The titer of extracellular virus reaches a maximum 36–48 h after infection. Infected cells undergo only limited cytopathic change during virus production with little or no change in the level of host protein synthesis. Long-term virus cultures are readily established.

Although arenavirus replication takes place in the host-cell cytoplasm, enucleated cells fail to support virus production. Specifically, the host-cell nucleus is required during the first 10 h of Pichinde virus infection of BHK-21 cells (Banerjee et al. 1976). Either enucleation removes a site of virus replication near the nuclear membrane or host nuclear products are required for viral replication. The latter is supported by the finding that α-amanitin, an inhibitor of host RNA polymerase II that is responsible for mRNA and hnRNA synthesis, prevents arenavirus replication. In contrast, actinomycin D, which primarily inhibits rRNA synthesis, has a lesser effect on Pichinde replication.

Host-cell ribosomes that become incorporated into nascent virions retain their capacity to catalyse protein synthesis, but are not necessary for virus replication (Leung and Rawls 1977). In Pichinde virus, hybrid molecules between viral RNA and host-cell ribosomal RNA have been observed (Shivraprakesh et al. 1988) but their functional significance is unclear. Host-cell ribosomal proteins and translation factors are definitely incorporated within virus but may simply be remnants of assembly complexes rather than the package of complete ribosome (Borden et al. 1998b).

Host-cell enzymes are essential for the maturation of arenavirus envelope glycoproteins. These are translated as a long precursor (GP-C) that undergoes glycosylation, transport, and proteolysis involving host-cell enzymes (Buchmeier and Oldstone 1979; reviewed in Burns and Buchmeier 1993). Initially, for LCMV, a 58-residue signal peptide is cleaved from the N terminus of GP-C. Further cleavage depends on glycosylation of the precursor in the Golgi or post-Golgi compartments with 5–6 *N*-linked glycosylations for the N-terminal portion of GP-C (to become GP-1) and 2 *N*-linked glycosylations for the C-terminal portion of GP-C (to become GP-2) (Wright et al. 1989). Cleavage by a furinlike protease occurs at Arg_{262}–Arg_{263}. This cleavage is followed by trimming of the N-terminal portion of GP-2 (Burns and Buchmeier 1993). A protein kinase activity capable of phosphorylating the nucleocapsid protein has been identified in preparations of LCMV (Howard and Buchmeier 1983), but it is not known whether this is a cellular or viral enzyme or if it has any essential function. Recently, it has also been shown that Lassa Gp precursor is cleaved in endoplasmic reticulum by the cellular subtilase SKI-1/S1P, an enzyme that has been

observed to be involved in cholesterol metabolism (Lenz et al. 2001). Moreover, since apparently only the cleaved glycoprotein is incorporated into virions, this cellular enzyme is necessary for the formation of infectious virus. Lassa GP-C is the first viral glycoprotein known to be processed by SKI-1/S1P and its tissue expression pattern in rats revealed highest levels of activity in liver, spleen, and adrenal glands and low levels in brain (Seidah et al. 1999). Accordingly, in human Lassa fever cases, higher viral titers are recovered from liver, spleen, lungs, kidneys, and adrenal but not from brain (Walker et al. 1982a). This finding suggests that specific inhibitors for SKI-1/S1P mediated cleavage of Lassa virus GP-C might lead to new therapeutical approaches for Lassa fever (Lenz et al. 2001).

POLYPEPTIDES: STRUCTURE AND FUNCTION

Arenavirus proteins include the 250-kDa RNA polymerase (L), the 11–14-kDa zinc-binding protein (Z) encoded on the L RNA, the 63-kDa nucleocapsid protein (N or NP) and the 75-kDa glycoprotein precursor (GP-C) encoded on the S RNA (see Figure 4). These four proteins account for the coding capacity of the virus without overlap (Salvato and Shimomaye 1989). The stoichiometry of proteins in the LCM virion has been determined by metabolic labeling (Salvato et al. 1992). Per virion, there are about 30 copies of L protein, 1500 copies of NP, 650 copies of GP-1, 650 copies of GP-2 and 450 copies of Z protein (Figure 8). According to cross-linking studies, NP and Z are associated (Salvato et al. 1992) and NP and GP-2 are associated (Burns and Buchmeier 1991). Recent immunoprecipitation and genetic studies reveal Z:L binding that explains the ability of Z to inhibit transcription (Jacamo et al. 2003).

NP is the most abundant virion protein as well as the most stable and abundant viral protein in infected cells. There are ca. 1500–2000 copies of NP per virion, or one copy per 10–20 bases of viral genomic RNA (Bishop 1990). Among the negative-strand viruses, the nucleocapsid proteins usually function as the primary structural protein of viral cores and in mediating the interaction of the RNA polymerase with the viral RNA. A phosphorylated form of NP has been detected late in acute infection and in greater abundance in persistently infected cells (Bruns et al. 1986), leading to the suggestion that phosphorylation of NP is associated with attenuation of virus production and persistence. Breakdown products of NP have also been detected both in infected cells and in virions. It is conceivable, but not yet demonstrated, that fragments of NP serve as minor structural proteins (Coto et al. 1993). A 28 kDa degradation product of NP has been identified within the nuclei of Pichinde virus-infected cells, but no significance can yet be assigned to this (Howard 1993).

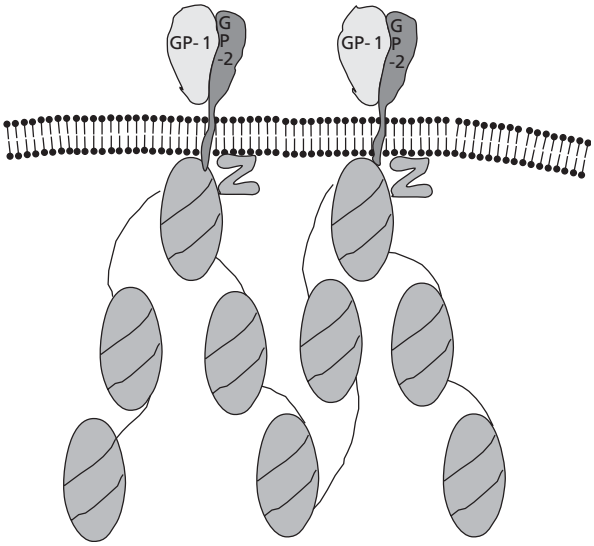

Figure 8 *Hypothetical scheme for the association of structural proteins in the LCM virion. The viral RNA is represented as a string winding around the beads that are the nucleocapsid protein molecules. The Z protein is depicted as a Z associated with the nucleocapsid proteins. GP-2 is anchored in the viral envelope and associated with NP. GP-1 is loosely associated with the surface of the virion. In each virion the proportions of Z, GP-1, and GP-2 in the virion are roughly equivalent, whereas NP is 3- to 5-fold more abundant. The polymerase or L protein accounts for only 30 molecules per virion. (Reproduced from Salvato 1993b)*

For LCMV, the envelope glycoprotein (GP) is synthesized as a 73-kDa precursor and cleaved into 43-kDa (GP-1) and 35-kDa (GP-2) polypeptides (Buchmeier and Oldstone 1979). Cleavage and maturation of the arenavirus glycoproteins, using host enzymes, has been described in the previous section. All arenaviruses that have been examined so far have potential cleavage sites in the glycoprotein precursor and two cleavage products that can be identified in protein gels. Tamiami and Tacaribe viruses are an exception in which only one cleavage product is observed in gels; however, the situation was clarified for Tacaribe virus when it was shown that the two cleavage products comigrate on gels but can be detected by analysis of the peptide termini (Burns and Buchmeier 1993).

The spikes of the virion are composed of GP-1 and GP-2: GP-2 is anchored in the membrane and associated with the nucleocapsid core through its C terminus and GP-1 is loosely attached to the virion surface through ionic interactions. Cross-linking studies indicate that GP-1 and GP-2 are present as homotetramers (Burns and Buchmeier 1991). Sequence analysis and antigenic cross-reactivity indicate that GP-2 contains a highly conserved sequence, whereas GP-1 contains the most variable sequence among the *Arenaviridae* (Weber and Buchmeier 1988; Clegg 1993). With Junin virus, rabbits and guinea-pigs inoculated with GP-2 produce neutralizing antibodies against the infectious virus (reviewed in

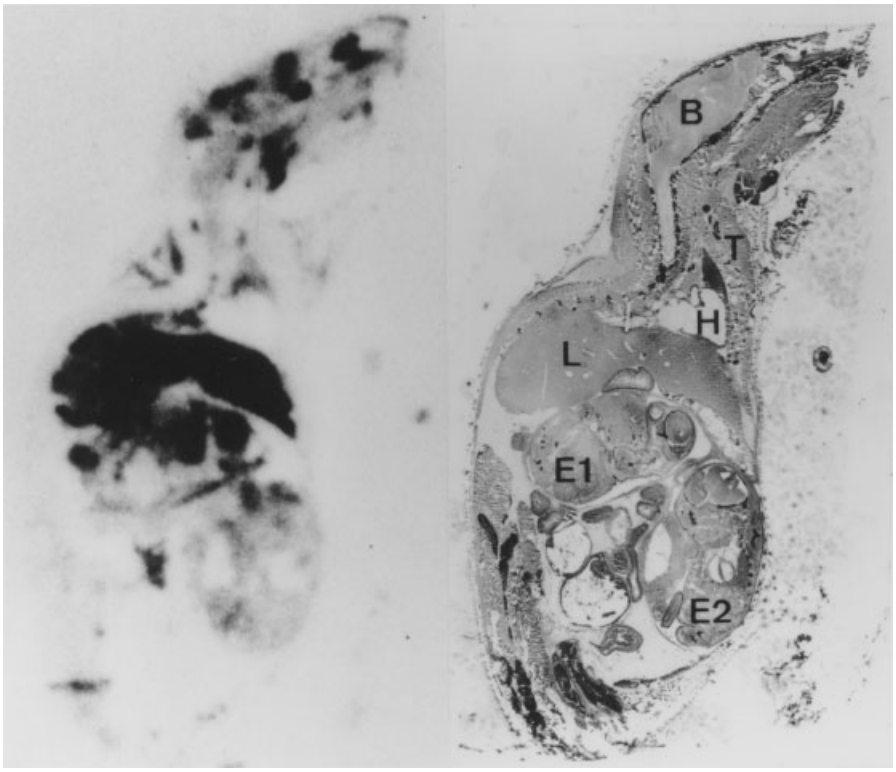

Figure 9 *Sagittal section of a pregnant mouse infected with LCMV. On the left is an autoradiograph of radioactive probes hybridizing to viral RNA within the section. On the right is the stained section: B, brain; E1, one embryo; E2, another embryo; H, heart; L, liver; T, thymus. (Reproduced from Southern et al. 1984)*

Martinez Peralta et al. 1993). In contrast, for LCMV, neutralizing antibodies predominately recognize conformational epitopes within GP-1 (Parekh and Buchmeier 1986) and this recognition depends on glycosylation and retention of disulphide bonds (Wright et al. 1989). It is likely that conformational changes of GP-1 expose domains on the spike glycoprotein that mediate virus entry into host cells (Di Simone et al. 1994).

The arenavirus L protein is the viral RNA-dependent RNA polymerase, is encoded in the 3′ ORF of the L RNA segment and has a molecular mass of 180–250 kDa. The L protein is a component of nucleocapsids since polymerase activity has been associated with these structures. The LAS L protein contains six motifs of conserved amino acids that have been found among arenavirus L proteins and core RNA-dependent RNA polymerase (RdRp) of other segmented negative-stranded (SNS) viruses (*Arena*-, *Bunya*-, and *Orthomyxoviridae*). (Lukashevich et al. 1997). Two regions found in the polymerases of arenaviruses and bunyaviruses are conserved in arenaviruses L proteins.

The zinc-binding protein of 11–14 kDa has a strongly conserved 'ring finger' motif in LCMV, Tacaribe, and Pichinde (Iapalucci et al. 1989; Salvato and Shimomaye 1989; Harnish et al. unpublished). This motif is characterized by the classic zinc-binding residues described in TFIIIA, and additional cysteine and histidine residues that help the molecule form a ring, i.e. C–X2–C–X(9–27)–C–X(1–3)–H–Y2–C–X2–C–X(4–48)–C–X2–C (Freemont 1993). Ring finger proteins generally have *trans*-regulatory functions and have been involved in protein–protein, protein–membrane and protein–nucleic acid interactions. The LCMV Z protein is a significant structural component of the virion and is able to bind isotopic zinc (Salvato and Shimomaye 1989; Salvato et al. 1992). Z protein has been detected in cytoplasm and nucleus of LCMV-infected cells and recent studies revealed that interacts with a nuclear oncoprotein, promyelocyte leukemia protein (PML), modulating the interferon response as well as ribosomal proteins (P0, P1, and P2) and transcription factors (eIF4E) performing regulatory functions in infected cells (Borden et al. 1997, 1998a, b; Campbell Dwyer et al. 2000; Djavani et al. 2001b). Garcin et al. (1993) showed that immunoprecipitation of Tacaribe Z protein blocked transcription whereas de la Torre's minigenome transcription system was inhibited by addition of excess of Z (Cornu and de la Torre, 2001, 2002). Also, the protein Z had a positive role on virus assembly using the same system (Lee and de la Torre 2002) Thus, the Z protein of the arenaviruses is most likely to be a matrix protein.

ANTIGENS

Highly accurate nucleic acid technologies (i.e. sequencing and RT-PCR) have recently superseded the use

of viral antigens in identification and classification of arenaviruses. Nevertheless, complement fixation (CF), immunodiffusion (ID), immunofluorescence (IF), enzyme-linked immunosorbent assay (ELISA), and neutralization/plaque-reduction assays have all been instrumental in the detection, diagnosis, characterization, and classification of arenaviruses (Bro-Jorgensen 1971; Brown and Kirk 1969; Chastel 1970; Geshwender et al. 1976; Simon 1970).

CF shows a strong relationship between Tacaribe, Junin, and Machupo viruses, and distant cross-reactivities between Pichinde and Tamiami viruses (Casals 1975; Casals et al. 1975; Rawls and Buchmeier 1975). By the CF test, LCMV and Lassa viruses are related to each other, but very distantly related to the New World arenaviruses. The complement-fixing antigen is probably a portion of the nucleocapsid protein (Howard 1993; Rawls and Leung 1979).

IF with antisera raised against heterologous viral antigens afforded the first evidence that Tacaribe and LCMV are related. Serological cross-reactivities between the 'type-specific' envelope proteins have been determined by IF assays in which unfixed cells, displaying viral envelope antigens, are suspended with antisera. Cross-reactivities between 'group-specific' nucleocapsid proteins are determined from acetone-fixed cells, because the primary antigen within infected cells is NP. Serological cross-reactions in patients with Bolivian and Argentine hemorrhagic fevers are detected by IF tests with fixed cultures. Acute phase and early convalescent sera have been particularly valuable. A great deal of cross-reactivity can be seen between Machupo and Junin viruses, closely followed by Tacaribe virus (Buchmeier et al. 1977).

IF has played an important role in arenavirus diagnosis. In the case of Lassa fever virus, infected cells have been fixed to glass slides that are stable for months and can be used for field work in Africa (McCormick 1987). Infected cells on slides can be treated with UV and γ-irradiation and with acetone to ensure that they are not infectious. ELISA has also been useful for diagnosis in the field, but requires more viral antigen than the fixed-cell slides.

Cross-neutralization is the most specific test of antigen relatedness between arenaviruses. Neutralizing antibodies to Lassa appear late in convalescent sera, but are usually too specific or too weak to be detected in cross-neutralization (Peters 1984). High titer animal sera can effect cross-neutralization between Junin, Tacaribe, and Machupo viruses, but cross-neutralization has not been observed between Junin and Machupo viruses with human convalescent sera, even though these are positive in CF assays. The sensitivity of the neutralization test can be increased for LCMV by adding complement or anti-γ-globulin to the test system. The incorporation of antibodies into the overlay for a plaque assay can also be used to detect neutralizing antibodies; for example, plaque size reduction was described for Pichinde virus (Chanas et al. 1980).

With the advent of monoclonal antibodies, many useful and specific reagents against arenavirus antigens became available. Initially they were used to demonstrate the relatedness or conservation of arenavirus antigens. Panels of monoclonal antibodies against LCMV and Pichinde virus showed distinct cross-reactivities with Lassa and Mopeia viruses (Buchmeier et al. 1981). Antibodies against GP-2 and NP are more broadly cross-reactive than antibodies against GP-1, which react only against a subset of the strains. For example, one LCMV GP-2 monoclonal cross-reacted with both Old World (LCMV, Lassa, Mopeia, and Mobala) and New World (Pichinde, Junin, Tacaribe, Amapari, Parana, and Machupo) viruses (Weber and Buchmeier 1988). In a similar comparison, monoclonals raised to Lassa virus were tested against Mopeia and Mobala viruses, and GP-2 cross-reactivity once again was notable (Gonzalez et al. 1984). Cross-reactivity of NP epitopes between Lassa and Mopeia has been confirmed, along with lesser reactivity to the envelope glycoprotein (Clegg and Lloyd 1984). Broad cross-reactivities observed between epitopes on Pichinde and Old World arenaviruses demonstrate that several surface antigens are conserved between the Old World and New World arenaviruses (Buchmeier et al. 1980b).

In recent studies, monoclonal and monospecific antibodies have been invaluable in determining the molecular structure and function of arenaviruses. For example, nucleic acid sequences have been confirmed to encode proteins by the use of peptide-specific antisera (Southern et al. 1987; Salvato et al. 1989), neutralizing antisera have been used to identify the viral structural proteins involved in neutralization (Burns and Buchmeier 1993, Martinez Peralta et al. 1993).

CLINICAL AND PATHOLOGICAL ASPECTS

CLINICAL MANIFESTATIONS

In animals

All arenaviruses establish persistent infection in the natural rodent host after virus infection in utero or within a few days of birth. Adult mice inoculated intracerebrally with LCMV develop tremor with characteristic extensor spasm of the legs and they finally go into convulsions and die (Oldstone 1987b). When adult mice are inoculated peripherally, the outcome is variable with a marked loss of body weight. Lassa virus causes a silent persistent infection in its natural reservoir *Mastomys natalensis,* in the same way that LCMV infects mice. In hamsters, LCMV causes symptoms similar to those in mice. Guinea-pigs infected with Junin virus develop hemorrhagic disease with extensive necrosis of lymphatic tissue and a late development of neurological

disease (Weissenbacher et al. 1975; Molinas et al. 1978). Guanarito virus causes mortality in suckling mice and adult guinea-pigs, but not in adult mice (Tesh et al. 1994). In rhesus and cynomolgus monkeys, LCMV and Lassa virus cause fever, anorexia, severe petechial rash on the face, progressive wasting and death within about 2 weeks, with a course similar to Lassa fever in humans (Jahrling et al. 1980; Peters et al. 1987). Similar manifestations have recently been described after the intravenous inoculation of rhesus macaques with a low dose (1 000 plaque forming units) of the LCMV WE strain (Lukashevich et al. 2002). Junin and Machupo virus infections of nonhuman primates simulate the disease in humans, with fever, anorexia, weight loss, and gastrointestinal symptoms. The animals die with cachexia and severe dehydration (Eddy et al. 1975; Kastello et al. 1976; Weissenbacher et al. 1979; Avila et al. 1987).

In humans

Arenavirus infections in humans range from a febrile disease with aseptic meningitis with LCMV (Armstrong and Sweet 1939) and Tacaribe (anecdotal laboratory-acquired infection in 1976; see Martinez Paralta et al. 1993) to total collapse and death with circulatory and respiratory failure with the hemorrhagic fever viruses: Lassa fever virus (Rose 1956; Buckley et al. 1970; Frame et al. 1970), Junin virus, Argentine hemorrhagic fever (Maiztegui 1975) and Machupo virus Bolivian hemorrhagic fever (Mackenzie et al. 1964; Johnson et al. 1965), Guanarito virus Venezuelan hemorrhagic fever (Peters et al. 1974) and Sabía virus infection (Coimbra and Nassar 1994). The arenavirus hemorrhagic fevers are often severe, generalized febrile diseases with multi-organ involvement and fatality rates of about 16–30 percent in untreated hospitalized patients, characterized by tissue and pulmonary edema with prominent hypovolemic shock and acute respiratory distress syndrome (Fisher-Hoch 1993). Several of the South American arenaviruses have been found by screening rodent populations but are not associated with human disease; for example, Oliveros virus is carried by 20–30 percent of *Bolomys obscuras* in the Argentine hemorrhagic fever areas (Mills et al. 1996).

LCMV infection may be asymptomatic, mild or moderately severe with central nervous system (CNS) manifestation. Lymphocytic choriomeningitis begins with fever, malaise, weakness, myalgia, and headache associated with photophobia. Anorexia, nausea, and dizziness are common (Farmer and Janeway 1942). It has also been reported that LCMV has teratogenic capacity (Baldridge et al. 1993; Barton et al. 1995)

The onset of Lassa fever is characterized by generalized symptoms, including high fever, joint pain, back pain, and severe headache, leading on to dry cough and exudative pharyngitis. In severe cases, patients have raised hematocrit (packed cell volume), vomiting and diarrhea (Fisher-Hoch et al. 1985; Johnson et al. 1987; McCormick et al. 1987a; Walker et al. 1982a). Edema and bleeding may occur together or independently. Acute neurological manifestations ranging from unilateral or bilateral deafness to moderate or severe diffuse encephalopathy with or without seizures are common in Lassa fever. A febrile, systemic illness typically progresses in 4 days to subacute or chronic neuropsychiatric syndromes, including generalized seizures, dystonia, and memory difficulties or seizures, agitation with personality and cognitive changes (McCormick et al. 1987a; Solbrig 1993). In pregnant women, Lassa fever is severe, especially during the third trimester, and fetal/neonatal loss is 87 percent (Price et al. 1988). In children, Lassa virus infection has been associated with a 'swollen baby syndrome' consisting of widespread edema, abdominal distension, and bleeding (Monson et al. 1987).

Argentine hemorrhagic fever, Bolivian hemorrhagic fever, Venezuelan hemorrhagic fever, and the newly isolated Sabía virus infection are clinically very similar (Mackenzie et al. 1964; Johnson et al. 1965; Peters et al. 1974; Maiztegui 1975; Weissenbacher et al. 1987; Coimbra and Nassar 1994). Symptoms include malaise, high fever, severe myalgia, arthralgia, anorexia, relative bradycardia, lumbar pain, epigastric pain, abdominal tenderness, conjunctivitis and retro-orbital pain, with photophobia. In severe cases there is nausea, vomiting, diarrhea, tremor, and convulsions (Vainrub and Salas 1994). Proteinuria, microscopic hematuria with subsequent oliguria, and uremia are common. Fatal cases show hemorrhagic disorders due to vascular collapse with hypotensive shock, hypothermia, and pulmonary edema. In contrast to Lassa fever, bleeding with severe thrombocytopenia is more common in Argentine and Bolivian hemorrhagic fevers (Fisher-Hoch 1993).

EPIDEMIOLOGY

Arenaviruses are zoonotic agents maintained within rodent hosts in a chronic carrier state. The majority of the rodents associated with arenaviruses are commensals or semi-commensals, living within human dwellings or in cultivated fields. The habitat preferences of each species dictate the epidemiological patterns of the diseases they cause in humans with regard to occupational, sexual, or seasonal bias (reviewed by Childs and Peters 1993).

In the case of LCMV, vertical transmission in utero is the major mechanism of viral maintenance in *Mus musculus* at the population level. Transmission through the gastrointestinal tract is the other possibility (Montali et al. 1993; Rai et al. 1996). Rodent-to-human infections probably occur through aerosols or contact with rodent blood, droplets, and fomites. Nosocomial spread of LCMV has not been reported. A longitudinal study in

the USA from 1941 to 1958 implicated LCMV infections in about 8 percent of the patients diagnosed with suspected viral meningitis, and serological studies have suggested an incidence of LCMV infection in the general population of up to 10–15 percent (Childs and Peters 1993). Most of these infections are probably mild or subclinical. Laboratory infections with LCMV are relatively common.

Human-to-human spread has been reported for Lassa fever in the community and in hospital settings (McCormick et al. 1987b), whereas only a few cases of nosocomial transmission have been reported for Bolivian hemorrhagic fever (Peters et al. 1974) and none for Argentine hemorrhagic fever virus. There have been reports suggestive of sexual transmission of Lassa and Machupo viruses from convalescing patients (Douglas et al. 1965). Aerosol spread and direct contact are the most likely routes of infection between humans. Neonates are at risk of infection through their mother's milk.

The aerosol stability of arenaviruses seems to be high. Studies with Lassa virus indicate a biological half-life of 55 min at 25°C and 30 percent relative humidity or 18 min at 25°C and 80 percent relative humidity (Stephenson et al. 1984). Arenaviruses are susceptible to heat and desiccation.

In natural primary hosts, arenaviruses can establish at least two types of chronic infections. LCMV, Junin, Machupo, and Lassa viruses can establish persistent infections resulting in long-term viremia with few signs of disease in carriers. Other arenaviruses such as Latino virus and Tamiami virus cause chronic infections without persistent viremia (Jennings et al. 1970; Webb et al. 1973). Strain and passage history of arenaviruses inoculated into experimental animals have a marked effect on lethality, tissue tropism, and development of persistent infection (Traub 1938; Dutko and Oldstone 1983). The dose of arenavirus in conjunction with the route of exposure and age of the host can have a critical effect on the type of infection that results (Webb et al. 1975).

PATHOGENESIS

In animals

Adult mice infected intracerebrally with LCMV develop an acute inflammatory leptomeningitis, and choroiditis leading to death within 6–10 days (Oldstone 1987a). When adult mice are inoculated peripherally, viremia peaks about 4–5 days after inoculation, usually causing widespread immune-mediated damage to the meninges, choroid plexus, and ependyma (Cole and Johnson 1975). LCMV is known to infect and replicate in virtually every organ examined, particularly in the spleen, liver, kidney, brain, lung, uterus, thymus, and lymph nodes (Figure 9). Immunopathology characteristic of acute murine infection with LCMV is described in the section entitled Immune response. In newborn mice, LCMV inoculation by any route leads to persistent infection. After replication in the brain, virus enters the circulation to reach tissues, serum, and urine. The pathogenesis of Lassa virus in mice is minimal and similar to infection by LCMV, whereas Junin and Machupo viruses may cause either illness and death or may induce persistence in newborn mice (Webb et al. 1975; Sabattini et al. 1977). Junin and Machupo viruses in their natural rodent hosts, Calomys spp., cause up to 50 percent fatality of infected suckling animals. Machupo virus renders the animals sterile, causes fetal mortality, and also induces hemolytic anemia with significant splenomegaly.

Histological studies of LCMV infection in hamsters and guinea-pigs show that the virus is pantropic, with high titers of virus and little evidence of histological damage. In guinea-pigs, Lassa virus causes myocarditis, pulmonary edema, and hepatocellular damage (Walker et al. 1975; Jahrling et al. 1982). Junin virus is mainly viscerotropic in guinea-pigs without evidence of an immunopathological mechanism. The animals develop hemorrhagic disease with extensive necrosis of lymphatic tissue (Weissenbacher et al. 1975; Molinas et al. 1978). Monkeys infected with Lassa virus have mild hepatic focal necrosis, pulmonary interstitial pneumonitis with interstitial edema, and focal adrenal cortical necrosis (Walker et al. 1982a). In rhesus and cynomolgus monkeys the infection causes death in 10–15 days due to vascular collapse and shock, with mild hemorrhage into mucosal surfaces (Fisher-Hoch et al. 1987). A primate model showing similar hemorrhagic fever was developed for the hepatotropic LCMV strain WE (Lukashevich et al., 2002, 2003).

In humans

The arenavirus hemorrhagic fevers in humans are often severe, generalized febrile diseases with multi-organ involvement. The hemostatic defect in these infections is characterized by platelet dysfunction and loss of integrity of the capillary bed. This presumably causes the leakage of fluids and macromolecules into the extravascular spaces and subsequent hemoconcentration, hypoalbuminemia, and hypovolemic shock. There is no evidence for major hepatorenal failure or organ destruction by direct viral replication. Renal damage in Argentine and Bolivian hemorrhagic fevers is characterized by structural damage in the distal tubular cells and collecting ducts (Cossio et al. 1975). Lungs show large areas of intra-alveolar or bronchial hemorrhage. Microscopic examinations reveal a general alteration in endothelial cells and mild edema of the vascular walls, with capillary swelling and perivascular hemorrhage (reviewed by Fisher-Hoch 1993). Necropsy findings

from a single case of Sabía virus infection show diffuse pulmonary edema and congestion with intraparenchymal hemorrhages, hepatic congestion with focal hemorrhage and necrosis, renal edema and acute tubular necrosis, splenic enlargement and congestion, and massive gastrointestinal hemorrhage (Coimbra and Nassar 1994).

The pathogenesis of CNS disease in arenavirus infections is poorly understood. Seizures, delirium, memory difficulties, and abnormal movements are the final common pathways of many metabolic changes. Failure of postmortem examinations to detect specific pathological changes in the brain of Lassa virus-infected individuals along with lower viral titers than other organs suggests that some of the neurological manifestations of these infections may not result from a direct viral effect but are due to some indirect cause (reviewed by Solbrig 1993). In 1998, Lukashevich et al. showed that Lassa virus could suppress inflammatory response in primates and in human cell cultures (Lukashevich et al. 1999). This is in contrast to guinea-pig studies (Maiztegui 1975) and in support of human studies showing that fatal infection tended to have less TNF, IP-10, and IL-8 (Mahanty et al. 2001)

IMMUNE RESPONSE

The LCMV murine model has proved to be invaluable for the study of acute and persistent infections in a natural host and has also brought to light several principles of viral immunobiology and viral immunopathology. As many of the studies on arenavirus immunology have been done in the LCMV murine model, the virus-specific immune responses in the LCMV context are summarized here.

Adult immunocompetent mice inoculated with LCMV either succumb to the disease or survive with permanent immunity. Neonatally infected mice or immunosuppressed mice inoculated with LCMV develop a lifelong persistent infection. Anti-LCMV antibodies are detectable by day 4 and LCMV-specific cytotoxic T lymphocytes (CTL) peak around 7–9 days after infection (Hotchin 1971; Lehmann-Grube 1971; Bro-Jorgensen and Volkert 1974).

Protection against an acute LCMV infection is mediated almost exclusively by $CD8^+$ CTLs (Zinkernagel and Doherty 1979; Buchmeier et al. 1980a; Lehmann-Grube et al. 1988). The same CTLs may also cause immunopathology (Hotchin 1962; Cole et al. 1972; Doherty and Zinkernagel 1974; Zinkernagel and Doherty 1979; Leist et al. 1988). The kinetics of viral spread and the T-cell response are important factors that affect the outcome of the disease (Hotchin 1962; Buchmeier et al. 1980a). After intracerebral infection, the T-cell immune response is protective only when a large number of T cells are recruited early, while relatively few choriomeningeal cells are infected. When virus spreads rapidly and too many choriomeningeal cells are infected, immune T cells cause extensive lysis and therefore lethal immunopathological disease (Oehen et al. 1991; Battegay et al. 1992).

During the acute LCMV infection, the H-2-restricted, LCMV-specific $CD8^+$ CTL response peaks at 7–9 days after infection (Marker and Volkert 1973; Zinkernagel and Doherty 1974). These responses are accompanied by and depend on high levels of *IL-2* gene transcription, IL-2 production and expression of the high affinity form of the IL-2 receptor (Kasaian and Biron 1990). A secondary stimulation of LCMV-immune mice with homologous virus results in a memory CTL response peaking earlier than in primary infections (Lehmann-Grube and Lohler 1981). The magnitude of secondary CTL response is often less than the acute response, probably because the virus is cleared so rapidly. $CD8^+$ cells have a functional autonomy during the immune response to LCMV infection and do not depend on the presence of the majority of $CD4^+$ cells to sustain either activation or proliferation in vivo (Kasaian et al. 1991).

In contrast to the fatal meningitis mediated by $CD8^+$ T cells, $CD4^+$ T cells mediate a less severe form of choriomeningitis in response to intracerebral LCMV infection. Evaluation of the immune response against LCMV in CD8-defective mice reveals a $CD4^+$ T cell-dependent immunopathology after intracerebral infection with LCMV and the clearance of LCMV by mechanisms independent of $CD8^+$ T cells (Fung-Leung et al. 1991).

Mice persistently infected with LCMV by congenital infection or neonatal inoculation do not develop a detectable CTL response and can be regarded as 'tolerant' at the level of CTLs. The characteristically subclinical persistent infections of these animals have given rise to the notion that persistence requires B-cell tolerance (Hotchin 1971). However, these mice are not completely tolerant to LCMV, because they make antibodies to all the LCMV structural proteins (Oldstone and Dixon 1967; Buchmeier et al. 1978).

LCMV infection in the mouse has been important for the study of $CD8^+$ T cells because it induces a large T-cell response that can be identified using ex vivo cytolytic assays and, more recently, Elispot and Tetramer assays, to confirm the size and specificity of the early expansion of T-cell populations. Tetrameric peptide–MHC-class-I complexes (tetramers) allow antigen-specific T cells to be tracked in time and space, as well as a detailed analysis of their surface phenotype (Altman et al. 1996).

Of all the potential peptides, one dominant epitope elicits a response up to 30 percent of the $CD8^+$ T cells in the spleen with little evidence of bystander activation (Klenerman et al. 2002). In several strains different epitopes have been identified with similarly dominant T-cell responses (Murali-Krishna et al. 1998; Gallimore et al. 1998).

The response of T cells to antigen during LCMV infection in the mouse seems to follow a bell-shaped curve with increasing antigen leading to increased T-cell activation. In conditions of extreme or prolonged antigenic stimulation, tetramer-positive T cells lose their function and then decline in number. This situation is reversible and cells recover if antigen load decreases. Lack of help, lack of costimulation and other factors might contribute to T-cell deletion as well (Ou et al. 2001).

In Lassa fever there is a substantial macrophage response, with little if any lymphocytic infiltrate. The antibodies directed against the glycoprotein and nucleocapsid protein appear early in the illness in Lassa fever, with a classic primary IgG and IgM response. The antibodies are present simultaneously with viremia in humans and primates (Fisher-Hoch et al. 1987; Johnson et al. 1987). Thus, though the antibodies are markers of acute illness, they are not involved in recovery. Neutralizing antibodies are found in only a minority of patients several months after the clearance of virus (Jahrling et al. 1980; Jahrling and Peters 1984). Thus, clearance of virus presumably depends on cell-mediated immunity. In contrast, IgG antibodies to Junin and Machupo viruses appear 12–30 days after onset and are usually associated with clinical improvement and virus clearance, and the therapeutic efficacy of immune plasma in patients with Junin infection is directly associated with the titer of neutralizing antibodies in the donor plasma (Peters et al. 1973; Enria et al. 1984). The role of cell-mediated immunity in viral clearance and subsequent protection from Junin and Machupo virus infections is not known.

IMMUNOPATHOLOGY

Efficient cell-mediated immunity is crucial for the recovery of a host from acute LCMV infection (Zinkernagel and Doherty 1979; Buchmeier et al. 1980a). In infections with a noncytopathic virus such as LCMV, the balance between the virus spread and the T-cell immune response determines whether either virus elimination (protection) or cell and tissue damage (immunopathology) predominates or whether a virus carrier state (no virus elimination, no cell and tissue damage) results. Acute LCM disease, chronic LCM-wasting disease and LCM carrier status in mice (Hotchin 1962; Zinkernagel and Doherty 1979; Buchmeier et al. 1980a) are examples of these varying equilibrium conditions between virus and immune response.

Effectors of immunopathology

Intraperitoneal or intravenous infection of adult mice with LCMV usually results in a virus-specific CTL response that clears the virus with long-lasting immunity, whereas intracerebral inoculation results in a lethal leptomeningitis associated with virus replication in the brain and an intense mononuclear cell infiltrate. Death and the associated meningitis are blocked if the mice are treated with thymectomy, immunosuppressive irradiation or immunosuppressive drugs such as cyclophosphamide; this led to the suggestion that the disease is mediated by the immune response (Haas and Stewart 1956; Rowe et al. 1963; Gilden et al. 1972). Subsequent investigations have supported the hypothesis that the pathology in acute LCMV disease is mediated by cellular immunity (Volkert and Lundstedt 1968; Cole et al. 1972; Gilden et al. 1972).

Interferon (IFN) increases the susceptibility of LCMV-infected fibroblasts to lysis by H-2-restricted CTLs (Bukowski and Welsh 1985). This enhanced lysis correlates with increased cell surface expression of MHC antigens but not of LCMV antigen. IFN-γ is an especially potent inducer of MHC expression in most cell types (Wong et al. 1984). This indicates that the limiting component in the lytic interaction is the histocompatibility antigen and that physiological influences on the expression of antigen may affect the progress of host-mediated disease. Treatment of adult mice infected intracerebrally with LCMV with antibody to IFN prevents their death, whereas untreated control mice succumb to the same dose of lethal LCMV, thus showing the role of IFN in the pathogenesis of cell damage in murine LCM (Pfau et al. 1983). The promyelocytic leukemia protein (PML) is a mediator of arenavirus sensitivity to IFN (Djavani et al. 2001a; Bonilla et al. 2002).

Murine LCMV infection is also considered the classic example of virus-induced immune complex disease. Persistent LCMV infection with circulating non-neutralizing antibodies in ratios and quantities that favor binding of complement and deposition in tissues results in immunopathology. This state is affected by host and viral genetic factors (Oldstone et al. 1983). Large quantities of deposited immune complexes along with IFN-γ seem to cause development of glomerulonephritis (Walker and Murphy 1987). Strains of mice characterized as intermediate IFN responders, such as outbred Swiss mice, have higher levels of circulating immune complexes and develop much more severe immune complex-associated glomerulonephritis than strains of low IFN responder mice, such as BALB/c mice, after LCMV infection (Woodrow et al. 1982). Antibodies to IFN diminish glomerular damage without affecting levels of circulating immune complexes (Pfau et al. 1983).

Progress of central nervous system pathology

$CD8^+$ T cells along with macrophages are thought to be the main cells that contribute to meningeal inflamma-

tion after LCMV infection (Allan et al. 1987). In addition, natural killer (NK) cells, $CD4^+$ T cells, neutrophils, and B cells are also present at the site of inflammation (Johnson et al. 1978). Large numbers of white blood cells, including CTLs, NK cells, and macrophages, are found in the cerebrospinal fluid (CSF), brain tissue, and meningeal exudate. Although the integrity of the blood–brain barrier is destroyed, the relatively non-lytic LCMV itself is unlikely to disrupt the barrier (Doherty 1973; Doherty and Zinkernagel 1974). It is more likely that the virus-induced IFN-γ initiates the infiltration of inflammatory cells across the blood–brain barrier.

The presence of CTLs in CSF has been shown by functional studies and by immunocytochemistry (Zinkernagel and Doherty 1973). CTL activity is also present in the CSF 3 days after immune-cell transfer to LCMV-infected, immunosuppressed animals. After CNS infection with LCMV, high levels of NK-cell activity are detected in CSF and cervical lymph nodes. However, meningitis presumably does not occur before development of T cell response, as NK cells probably do not play an essential role in LCMV-induced immunopathology (Allan and Doherty 1986). NK cells do not influence LCMV synthesis in vivo, but do decrease the level of Pichinde virus (Welsh 1987; Brutkiewicz and Welsh 1995).

The CTLs present in cyclophosphamide-suppressed LCMV-infected mice after passive transfer of immune cells are of donor and not of recipient origin. So $CD8^+$ T cells also seem to be essential for triggering infiltration into the CNS. Presumably, for a maximal inflammatory process to occur, MHC class I-restricted $CD8^+$ T cells proliferate first in the peripheral lymphoid tissue and then enter the brain after recognition of MHC class I-compatible infected cells at the blood–CSF barrier (reviewed by Allan et al. 1987).

Immunosuppressed mice that survive an ordinarily lethal dose of LCMV develop acute LCM disease and die when reconstituted with syngeneic LCMV-specific immune T cells (Gilden et al. 1972). Thus, it is possible to imitate the immunopathology observed in acute LCMV infection by inoculating LCMV-specific H-2-restricted CTLs into carrier mice, which in turn cause either viral clearance and recovery or CTL-mediated immunopathology and death (Allan and Doherty 1985). $CD8^+$ T cells act directly rather than by the recruitment of circulating monocytes. Lethal LCM can be prevented in the uninfected mouse by intracerebral inoculation of cloned $CD8^+$ T cells together with the virus (Baenziger et al. 1986). The co-injected $CD8^+$ T cells gradually eliminate virus-infected cells without causing the massive inflammation associated with acute LCM disease. Severe meningitis ensues in adoptive transfer of LCMV-specific CTLs only when there is matching of MHC class I antigens between donor and recipient mice. In comparison, compatibility of MHC class II antigens is less important (Doherty et al. 1976; Allan and Doherty 1985).

Immunosuppression

MECHANISM OF IMMUNOSUPPRESSION

Acute infection of adult mice with LCMV leads to a general suppression of the immunological and mitogenic responses in vivo and in vitro, which persists for 2–3 months after infection (Mims and Wainwright 1968; Bro-Jorgensen and Volkert 1972; Jacobs and Cole 1976; Brenan and Zinkernagel 1983). Although different mechanisms have been postulated to explain this phenomenon, it is still poorly defined. LCMV infects different types of lymphocytes (Gartner et al. 1986; Rosenthal et al. 1986; Ahmed et al. 1987b) and macrophages (Mims and Subrahmanyan 1966; Zinkernagel and Doherty 1979). The ability of LCMV to induce a virus carrier state conatally or neonatally and in adult mice may be due to these particular tropisms of LCMV (Ahmed et al. 1987b). Depending on the virus isolate, the virus dose, the time after infection, and the mouse strain infected, LCMV can cause a severe immune deficiency, rendering the mice more susceptible to secondary infections.

Mice persistently infected with LCMV are deficient in generating LCMV-specific CTLs and delayed type hypersensitivity responses and also make low levels of antibodies against LCMV (Buchmeier et al. 1980a). LCMV-specific immune responses are inhibited by a lack of appropriate T-helper cells, because although deletion of $CD4^+$ T cells in a transgenic mouse model does not impair the primary $CD8^+$ LCMV-specific CTL response (Rahemtulla et al. 1991) it does impair T-cell memory (Matloubian et al. 1994). The different levels of cytokines in the brain and sera of acutely and persistently infected mice indicate that the two types of infections probably activate different types of cells.

A mechanism for generalized immunosuppression has been elucidated in the case of a particular LCMV isolate. For this isolate, LCMV Armstrong clone 13 (Ahmed et al. 1984), virus replicates to high titer in the spleen, causing immune-mediated destruction of dendritic cells; hence loss of the cells needed for immune responses to other pathogens (Tishon et al. 1993; Borrow et al. 1995). Clonal deletion of LCMV-specific CTLs may occur subsequently (Moskophidis et al. 1993). The long-term effect of clone 13 infection is that reduced immune response capacity allows the virus to persist, in contrast to infection with other isolates of this strain that are cleared within weeks by a vigorous cellular immune response (Salvato et al. 1991). The persistent and rapidly cleared isolates of LCMV Armstrong are analogous to the Docile (viscerotropic) and Aggressive (neurotropic) isolates of LCMV UBC in which docility is associated with the tendency for high titer replication in the viscera that leads to suppression of the CTL response and persistent infection (Thomsen and Pfau 1993). It is important to note that viral tropism

is crucial to the pathogenesis in these cases. The different tropisms of LCMV Armstrong and its variant isolate, clone 13, are shown in Figure 10.

Suppression of cell-mediated immunity

LCMV infection causes suppression of responses to T-dependent antigens in vivo (Mims and Wainwright 1968) and to allografts (Lehmann-Grube et al. 1972; Guttler et al. 1975). This may be due to a decreased number of mature T lymphocytes in lymphoid organs as a result of an alteration of T-progenitor cells in the bone marrow (Bro-Jorgensen and Volkert 1972; Thomsen et al. 1982). Alternatively, it is suggested that the immunosuppression may be related to the lysis of infected T lymphocytes and macrophages by virus-specific CTLs (Silberman et al. 1978). In addition to unresponsiveness to antigens, the proliferative response to T- and B-cell mitogens is also depressed and a virus-induced macrophage defect is probably responsible for the abortive collaboration with T lymphocytes (Jacobs and Cole 1976).

Suppression of humoral immunity

The suppression of T-independent IgM and a strictly T help-dependent IgG immune response against a second infectious agent is observed in immunocompetent adult mice infected with LCMV but not in tolerant LCMV carrier mice or LCMV-infected mice that have been depleted of $CD8^+$ T cells with monoclonal antibodies. Thus, the immune suppression is due not to LCMV itself nor to IFN induced by it but rather to the $CD8^+$ T cell-dependent immune response against LCMV (Leist et al. 1988).

Studies of the kinetics of T cell-mediated immunosuppressive effects of LCMV infection on primary and secondary antibody responses (to Vesicular stomatitis virus (VSV)) show that LCMV-WE induced immunosuppression is absolute for primary IgG responses induced during a limited time between days 2 and 11 after LCMV infection. The kinetics of induction of the T cell-independent IgM responses closely follow that of a normal CTL response to LCMV-WE (Roost et al. 1988). LCMV infection on the same day or before (but not after) VSV infection leads to suppression of IgG responses to VSV. However, primed IgG responses are not suppressed by a subsequent LCMV-WE infection and immunosuppression is not antigen specific but general (Ruedi et al. 1990). LCMV-induced suppression is absolute to the extent that priming does not occur, since subsequent challenge with the identical VSV serotype triggers a strictly primary response.

The severity and duration of immunosuppressiveness depend on the virus dose, the virus isolate, and the mouse strain used. LCMV-WE and LCMV Docile are the most and LCMV Armstrong the least immunosuppressive. Mouse strains differ considerably with respect to extent of suppression, depending on both the MHC and non-MHC genes. H-2q and H-2k mice seem to be more susceptible to immune suppression than H-2b or H-2d mice (Roost et al. 1988).

DIAGNOSIS

Diagnosis of arenavirus infection relies mainly on isolation and subsequent identification of the virus. Serological tests can also be used to detect specific antibodies or antigens.

Virus can be isolated mainly from the blood or serum. In addition, throat swabs, CSF, urine, breast milk, or other tissues taken by biopsy or at necropsy can also be used (Monath et al. 1974; Walker et al. 1982b; Johnson et al. 1987). The most successful system for isolating arenaviruses has proved to be cell culture. In addition to cell culture, laboratory animals such as suckling mice, guinea-pigs, and hamsters can also be used, although they are more expensive and increased safety precautions are necessary. The probability and timing of virus isolation vary with each arenavirus (Table 2).

Differential diagnosis for arenavirus infections, especially for Lassa fever, includes bacterial septicemia, typhoid, paratyphoid, typhus, trypanosomiasis,

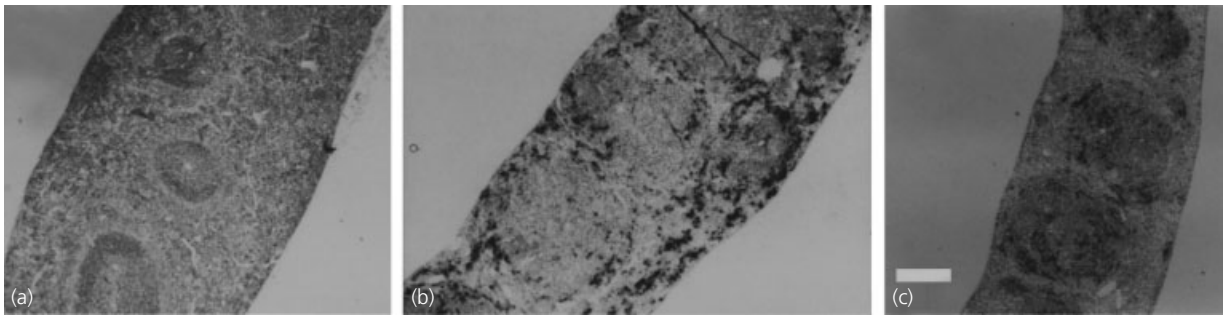

Figure 10 *Localization of LCMV nucleic acids in murine spleen by in situ hybridization with ^{35}S riboprobe specific for NP mRNA.* **(a)** *Spleen section from an uninfected control mouse (BALB/c ByJ).* **(b)** *Spleen section from a mouse infected IV with LCMV Armstrong for 3 days.* **(c)** *Spleen section from a mouse infected IV with the clone 13 variant of LCMV Armstrong for 3 days. Table 2 *Arenavirus isolation from tissue specimens at different stages of illness*

Virus	Tissue specimen	Stage of illness
LCMV	Blood	Initial febrile stage
	CSF	During acute illness
Junin	Blood	Up to 8 days in milder cases, up to 2 weeks in severely ill patients
	Throat swab	During acute illness
	Breast milk	During acute illness
Machupo	Blood	Up to 2 weeks (intermittent viremia)
	Throat swabs	Sporadic detection
Lassa	Blood	3–5 days in milder cases, up to 4 weeks in severely ill patients
	Throat swabs	Days 5–12 of illness
	Breast milk	During acute illness
	CSF	During acute illness
	Pleural transudate	During acute illness
	Pericardial transudate	During acute illness
	Urine	Up to 1– 2 months

Data adapted from McCormick (1990).

streptococcal pharyngitis, leptospirosis, malignant malaria, and other viral hemorrhagic fevers (Howard and Simpson 1990). Nucleic acid amplification by RT-PCR along with Southern blot hybridization with virus-specific DNA probe can be used as an early, rapid, and sensitive method for detecting arenavirus nucleic acid in peripheral blood mononuclear cells (PBMC) as well as from other tissues. Studies with Junin virus-infected PBMCs and tissues have shown that this assay allows detection of Junin virus RNA in RNA extracted from 100 μl of whole blood by guanidinium thiocyanate disruption and acid phenol extraction. As little as 0.01 pfu of Junin virus can be detected in a blood sample by this assay (Bockstahler et al. 1992; Lozano et al. 1993). In situ hybridization by viral sequence-specific radioactive probes can be done directly on biopsy or autopsy specimens to detect viral RNA and has proved to be highly sensitive in experimental LCMV infections of mice (see Figure 9).

Antibodies to arenaviruses can be detected in serum by a variety of serological methods, including IF assay, ELISA, immunoperoxidase labeling, radioimmunoassay, reverse phase hemagglutination assay, and hemagglutination inhibition tests. The complement fixation test is now rarely used because it is less sensitive than other methods (serological tests and antibody levels in arenavirus infections have been reviewed by McCormick 1990). IF is often used in serological diagnoses to detect arenavirus antigens in cell monolayers that have been exposed to suspect sera. At present, ELISA is increasingly used for the diagnosis of arenavirus infections. Alternatively, known antiserum or monoclonal antibodies can be used to detect viral antigens in biopsy or necropsy materials by immunohistochemical techniques.

PROPHYLAXIS

The development of a safe and effective vaccine for arenavirus infections of humans has proved difficult. Several killed and live-attenuated vaccines have been tested for Lassa, Junin, and Machupo viruses, none of which has proved suitable for widespread human use. Many of these vaccines are still in the stage of animal trials. A new live-attenuated Junin virus vaccine, Candid:1, has been developed which has been shown to be safe and immunogenic in nonhuman primates (Barrera Oro and McKee 1991; Contigiani et al. 1991; McKee et al. 1993). Laboratory animals infected with various avirulent viruses serologically related to Lassa virus, including LCMV, Mopeia, and Mobala viruses, survived a subsequent challenge with virulent Lassa virus (Walker et al. 1982a; Jahrling and Peters 1986). Similar strategies for protection against Junin virus with heterologous live vaccines have repeatedly demonstrated protection against Junin virus in guinea-pigs and hamsters (reviewed by Barrera Oro and McKee 1991). Other vaccine trials with inactivated Lassa and Machupo viruses have given mixed results, although they are immunogenic. Immunization with inactivated Lassa virus protects *Papio hamadryas* monkeys from a subsequent challenge with Lassa virus (Krasnianski et al. 1993), but fails to protect rhesus monkeys even though there is a secondary, high titer antibody response to the major structural proteins of Lassa virus in these vaccinated monkeys (McCormick et al. 1992).

For Lassa virus, a killed antigen vaccine has proved ineffective and an attenuated virus vaccine is not available, so a live recombinant virus vaccine provides a very attractive alternative. Recombinant vaccinia virus vaccines, which express either the Lassa virus nucleoprotein or the glycoprotein gene, successfully protect guinea pigs from a lethal Lassa virus infection, but offer incomplete protection in primates (Auperin et al. 1988; Morrison et al. 1989; Auperin 1993). Fisher-Hoch et al. (2000) have tested a variety of Lassa vaccines delivered to nonhuman primates via the NYBH vaccinia vector. In this study, the authors described the outcome after the

vaccination of 44 monkeys with Mopeia or with vaccinia expressing Lassa S segment genes (*G1*, *G2*, *N*, *G1+G2* or combinations of them). A third of the monkeys were Cynomolgus macaques and the remainder were rhesus and all of them were challenged with a lethal dose (10^5 pfu) of Lassa (Josiah strain). The data indicate that vaccines delivering all genes of the Lassa S RNA (both *N* and *G*) are more protective than vaccines with only the glycoprotein genes and, later, these are more protective than vaccines with only the *N* gene. From these experiments it is apparently clear that animals with high titers of neutralizing antibodies are not protected whereas others that survived did not show high levels of neutralizing antibodies, this finding supports the need for cellular immune response to protect against the Lassa challenge (Fisher-Hoch et al. 2000). A weak but measurable cross-protection against LCMV intracranial challenge can be mediated by Lassa-specific $CD4^+$ T cells (La Posta et al. 1993; Djavani et al. 2000, 2001b). Vaccine trials so far have suggested that cell-mediated immune response must be activated to protect against challenge with arenaviruses.

Immunization with recombinant vaccinia virus that expresses the LCMV glycoprotein (VV GP) or nucleoprotein (VV NP) protects mice from LCM disease by induction of a protective CTL response in an H-2 haplotype-dependent manner (Hany and Oehen 1989; Klavinskis et al. 1990; Oehen et al. 1991). Mice can be specifically protected by subcutaneous inoculation of recombinant LCMV proteins (GP or NP) or just the T-cell epitope of the LCMV nucleoprotein as an unmodified free synthetic peptide in incomplete Freund's adjuvant (Schulz et al. 1991; Bachmann et al. 1994). Vaccination with DNA encoding the LCMV nucleoprotein or the glycoprotein also confers protection against lethal LCMV challenge and against persistent LCMV infection in an MHC-dependent manner by priming $CD8^+$ cytotoxic lymphocytes (Martins et al. 1995; Yokoyama et al. 1995).

In certain circumstances however, immunization with VV GP or VV NP aggravates disease. For example, BALB/C mice infected with a high dose of the LCMV Docile isolate usually survive, unless they are preinjected with VV NP or VV GP (Oehen et al. 1991). This suggests that low level immunization may accelerate development of disease. Vaccination may shift the balance from low (i.e. late) to high (i.e. early) responder status and may therefore prevent immunopathologically mediated disease, or it may shift the balance only slightly from a nonresponsive asymptomatic carrier to a low or intermediate responder status to cause immunopathology. Thus, as well as illustrating the potential value of CTL vaccines, these vaccine studies also highlight the limitations of subunit vaccines. To protect an outbred population in an MHC-restricted fashion, it will be necessary to make a vaccine that consists of a cocktail of relevant peptides and to ensure that none of its components aggravates the disease in a subsequent virus challenge.

TREATMENT

Immunotherapy

LCMV-induced persistent infection in mice is a classic example of viral persistence and serves as a model to study basic principles of immune clearance in persistent and disseminated infections in general. This model system makes it possible to test the potential of specific immune therapy to clear virus from a chronically infected host and to study the effector mechanisms responsible for clearing such infections.

Volkert (1963) was the first to show that the adoptive transfer of spleen cells from LCMV-challenged immune adult mice results in reduction of infectious virus in carrier mice. This has been confirmed by a number of workers (Gilden et al. 1972; Allan and Doherty 1985; Baenziger et al. 1986). Distinct patterns of viral clearance and histopathology are observed in different organs after adaptive immunotherapy of persistently infected (carrier) mice. The clearance of viral materials from the CNS is distinct in pattern and timing with clearance from other organs. Clearance from the liver, lung, spleen, lymph nodes, pancreas etc. occurs within 30 days, whereas in the brain, infectious virus is eliminated but viral antigen persists up to 90 days after immunotherapy (Ahmed et al. 1987a). The urinary system is the most resistant to immunotherapy, and the viral antigen is localized within the renal tubules in the form of antigen–antibody complexes (Oldstone and Dixon 1967).

Clearance of viral materials (infectious virus, viral nucleic acid and proteins) from several organs of persistently infected mice probably occurs by reconstitution of LCMV-specific CTLs that have malfunctioned or have been deleted during viral infection. By using mice that are recombinant in the H-2 region and by selective depletion of lymphocyte subpopulations, it has been shown that viral clearance is mediated by cooperation between virus-specific $CD8^+$ T cells and nonspecific bone marrow-derived mononuclear cells from the carrier host (Ahmed et al. 1987b). The effector mechanisms responsible for eliminating the persistent and disseminated LCMV infection of mice are dependent on the lytic ability of CTLs, because perforin-negative transgenic mice are unable to clear infection (Kagi et al. 1994).

Early success of Lassa virus immune plasma in the treatment of Lassa fever (Leifer et al. 1970) and immunotherapy of Machupo virus infections in primates (Eddy et al. 1975) showed promise for the treatment of arenavirus infections in humans. Convalescent phase plasma from Junin virus patients reduced mortality from 16 to 1 percent in those who were treated in the first 8 days of illness (Maiztegui et al. 1979), and the efficacy of

the plasma seemed to be directly related to the concentration of neutralizing antibodies of the plasma. However, a better understanding of the limitations of this approach and reduced success in subsequent cases have restricted its use. A late neurological syndrome developed 4–6 weeks after the onset of acute illness in about 10 percent of the cases treated with Junin virus immune plasma. Passive antibody therapy depends on collection of plasma from people known to have had the disease, testing the plasma or screening the donor for antibodies to bloodborne agents such as hepatitis, and proper storage of plasma until it is used. In addition, the existence of HIV and other retroviral diseases transmissible by blood products has made the further screening of plasma mandatory before use. A study of combined antibody and ribavirin therapy has been performed in the mouse model (Seiler et al. 2000).

Antiviral agents

The antiviral drug ribavirin has proved effective in the treatment of Lassa fever in laboratory animals (Jahrling et al. 1980; Jahrling et al. 1984) and in humans (McCormick et al. 1986), especially when administered during the first 6 days after the onset of illness. Later, the pathogenesis of the infection is less reversible. Patients presenting late in disease require more effective clinical management of physiological dysfunction and need other drugs which may be used to stabilize the state of shock sufficiently long to facilitate recovery and survival. Ribavirin is perhaps more effective if given intravenously than orally (McCormick et al. 1986; McCormick 1990). It is the drug of choice for treatment and for prophylaxis in cases of possible exposure to Lassa virus, in laboratory or hospitals. Studies with Junin virus infections indicate that ribavirin may also have beneficial effect in Argentine hemorrhagic fever (Enria and Maiztegui 1994). A single case of laboratory-acquired Sabía virus infection was successfully treated with intravenous ribavirin (Barry et al. 1995) at a dosage recommended by the Centers for Disease Control and Prevention (CDC) for other arenavirus infections (a loading dose of 30 mg/kg body weight, followed by a dose of 15 mg/kg every 6 h for 4 days, and then by a dose of 7.5 mg/kg 3 times daily for 6 days).

In addition, fluid, electrolyte, and osmotic imbalances must be corrected in anticipation of the development of clinical shock and broad spectrum antibiotics administered to prevent secondary bacterial infections. However, even vigorous support of this kind may be insufficient to prevent fatal progression of disease.

Properties of filoviruses	1	Clinical and pathological aspects	9
Filovirus replication	7	References	14

PROPERTIES OF FILOVIRUSES

Introduction

In 1967, an outbreak of viral hemorrhagic fever occurred among laboratory workers in Europe exposed to tissues and blood from African green monkeys (*Cercopithecus aethiops*) imported from Uganda (Siegert et al. 1967; Martini and Siegert 1971). The virus, which had been isolated from a number of patients, has been called Marburg virus (MARV), after the city with the first reported cases. This episode marked the first identified outbreak of disease caused by a member of a group of viruses that have been classified in the family *Filoviridae*.

It was nearly a decade later, in 1976, when two other major filovirus outbreaks occurred in southern Sudan and northern Zaire (now Democratic Republic of the Congo). These outbreaks occurred simultaneously, but involved two biologically distinct species, Sudan ebolavirus (SEBOV) and Zaire ebolavirus (ZEBOV), of a new filovirus, Ebola virus (EBOV) (World Health Organization 1978a, 1978b; McCormick et al. 1983). In 1989, a third species of Reston ebolavirus (REBOV) emerged as the causative agent of an epizootic among a group of cynomolgus monkeys (*Macaca fascicularis*) imported from the Philippines into the United States (Jahrling et al. 1990). A similar epizootic occurred in 1992 when cynomolgus monkeys were imported into Italy from the same supplier who shipped the 1989 monkeys to the USA (World Health Organization 1992). In contrast to other human filoviruses, REBOV seemed to be less pathogenic, and no disease occurred in four humans who were infected with this species of EBOV (Peters et al. 1993). This is also reflected in a lower pathogenicity for nonhuman primates (Fisher-Hoch and Brammer 1992). EBOV was also detected in western Africa (Ivory Coast) in 1994, when a single human case was identified and a novel species Côte d'Ivoire ebolavirus (CIEBOV) was isolated (LeGuenno et al. 1995). This person was presumed to have been infected with EBOV while she was performing a necropsy on a wild chimpanzee, whose troop had undergone increased mortality, presumably due to EBOV disease.

In the past years EBOV and MARV have caused several major outbreaks of hemorrhagic fever in Central Africa. In 1995 EBOV re-emerged in the Democratic Republic of the Congo, causing a severe outbreak of hemorrhagic fever in the city of Kikwit and surrounding villages in Bandundu Province. A total of 315 cases of EBOV hemorrhagic fever were reported, of whom 244 died (77 percent) (World Health Organization 1995a). Molecular analyses identified the causative agent as ZEBOV, the glycoprotein gene differing by only 1.6 percent from the virus that caused the 1976 outbreak in northern Zaire (Democratic Republic of the Congo) (Sanchez et al. 1996). From 1994 to 1997 Gabon has suffered from three EBOV epidemics that occurred in the northeastern part of the country (Makokou). Virus isolation and sequence analysis demonstrated that all epidemics were caused by ZEBOV (Georges et al. 1999). In 1998, MARV emerged in the northern part of the Democratic Republic of the Congo near the border to Uganda and Sudan. More than 100 cases were reported with a mortality of about 70 percent (Muyembe-Tamfum 2000; Nichol 2000; Bausch et al. 2003). In October 2000, EBOV emerged in northeastern Uganda. The virus has been identified as species

SEBOV. Four hundred and twenty-five cases were confirmed with 224 deaths (World Health Organization 2001). There is currently (spring 2003) an EBOV outbreak ongoing in Congo-Brezaville that has so far claimed more than 100 human lives and has killed large parts of the local gorilla and chimpanzee population.

In addition to the major outbreaks described above, sporadic cases of filovirus hemorrhagic fever in humans have occurred in various parts of Africa. Incidences of filovirus disease in humans that have been confirmed by virus isolation are summarized in Table 1.

Classification

Filoviruses are classified in the order *Mononegavirales*, a large group of viruses that have nonsegmented negative-strand (NNS) RNA as their genomes. The family *Filoviridae* was created on the basis of unique morphologic, morphogenetic, physicochemical, and biological features of its members (Kiley et al. 1982). The family harbors two genera, *Marburgvirus* and *Ebolavirus*. The genus *Marburgvirus* is more homogeneous and consists of only a single species, but at least two different genetic lineages co-exist (Kiley et al. 1988; van Regenmortel et al. 2000; Sanchez et al. 1998a). The genus *Ebolavirus*, however, can be subdivided into four species: *Côte d'Ivoire*, *Reston*, *Sudan*, and *Zaire* (CIEBOV, REBOV, SEBOV, ZEBOV) (Feldmann et al. 1997; Sanchez et al. 1996; Feldmann et al. 2004). Nucleotide sequence comparison between MARV and EBOV shows only scattered similarities, which is in contrast to strong similarities seen between amino acid sequences of the structural proteins. Despite this amino acid similarity, there is no indication that there is any significant serological (antigenic) cross-reactivity between EBOV and MARV, but the species of EBOV share common epitopes (Richman et al. 1983; Feldmann et al. 1994). It may be that the nucleotide sequences of these agents diverged at some point in the distant past but the structural proteins have maintained similar structures and functions. Significant differences within the genus *Ebolavirus* were first noted from peptide and oligonucleotide mapping (Buchmeier et al. 1983; Cox et al. 1983), and have been confirmed by sequence analysis of the glycoprotein genes (Sanchez et al. 1996). The study by Sanchez et al. showed that all four species differ from each other to a comparable extent (37–41 percent nucleotide differences). This suggests that filoviruses have evolved into specific niches and may reflect a similar divergence in the natural hosts, assuming they have co-evolved.

Molecular analyses of the genomes of filoviruses have clearly demonstrated a close genetic relationship to the other families of the order, especially the *Rhabdoviridae* and *Paramyxoviridae*. All NNS RNA viruses share a similar genome organization: the more conserved genes that encode core and L proteins are located at the 3′ and 5′ ends, respectively, of the genomic RNA. In between these conserved areas is a more variable region that generally contains genes encoding envelope and certain membrane-associated proteins. The only exception occurs in the genomes of filoviruses, which contain a minor nucleocapsid-associated protein (VP30) in this region (Figure 1). Filovirus genomes are more complex than those of rhabdoviruses, and their organization is more like those of members of the genera *Respovirus* and *Morbillivirus* of *Paramyxoviridae*. This relationship was confirmed by comparisons of the deduced amino acid sequences of the nucleoprotein and L protein (Feldmann et al. 1993; Sanchez et al. 1993).

In terms of biohazard classification, filoviruses are classified as 'Biosafety Level 4' agents on the basis of their high mortality rate, person-to-person transmission, potential aerosol infectivity and absence of vaccines or chemotherapeutic agents. Maximum containment is required for all laboratory work with infectious material (Centers for Disease Control and Prevention 1993).

Morphology and structure

Filovirus virions are bacilliform in shape, but particles can also appear as branched, circular, U or 6-shaped and long filamentous forms. This morphology is unusual for viruses and has been important in the classification and nomenclature (Latin *filum*: thread) (Figure 1a,b). Virions vary greatly in length but show a uniform diameter of approximately 80 nm. Family members differ in length of virion particles but seem to be very similar in morphology. Peak infectivity has been associated with particles of 665 nm for MARV and 805 nm for EBOV. Virions are composed of a central core formed by a nucleocapsid or ribonucleoprotein (RNP) complex, which is surrounded by a lipid envelope derived from the host cell plasma membrane. Electron micrographs reveal an axial channel (10–15 nm in diameter) that is surrounded by a central dark layer (20 nm in diameter) and an outer helical layer (50 nm in diameter) with cross-striations of 5 nm intervals. Spikes, approximately 7 nm in diameter and spaced at intervals of approximately 10 nm are seen as globular structures on the surface of virions (Siegert et al. 1967; Peters et al. 1971; Murphy et al. 1978; Kiley et al. 1982).

The RNP complex is composed of a genomic RNA molecule and four of the seven virion structural proteins: the nucleoprotein (NP), virion structural protein (VP) 30, VP35, and the large (L) protein (Becker et al. 1998) (see Figure 1b). The genomic RNA has a molecular weight of 4 200 kDa and constitutes 1.1 percent of the virion mass (Regnery et al. 1980). The three remaining structural proteins are membrane-associated; the glycoprotein (GP) shows a type I transmembrane protein profile (Will et al. 1993; Sanchez et al. 1998b), while the VP24 and VP40 are probably located at the inner side of the

Table 1 *Outbreaks of filoviral hemorrhagic fever*

Location	Year	Virus/species	Cases (mortality)	Reference	Epidemiology
Germany/Yugoslavia	1967	MARV	32 (23%)[a]	Martini and Siegert (1971)	Imported monkeys from Uganda source of most human infections
Zimbabwe	1975	MARV	3 (33%)	Gear et al. (1975)	Unknown origin; index case infected in Zimbabwe; secondary cases were infected in South Africa
Southern Sudan	1976	SEBOV	284 (53%)	World Health Organization (1978a)	Unknown origin; spread mainly by close contact; nosocomial transmission and infection of medical staff
Northern Democratic Republic of the Congo	1976	ZEBOV	318 (88%)	World Health Organization (1978b)	Unknown origin; spread by close contact and by use of contaminated needles and syringes in hospitals
Tandala, Democratic Republic of the Congo	1977	ZEBOV	1 (100%)	Heymann et al. (1980)	Unknown origin; single case in missionary hospital; other cases may have occurred nearby
Southern Sudan	1979	SEBOV	34 (65%)	Baron et al. (1983)	Unknown origin; recurrent outbreak at the same site as the 1976 outbreak
Kenya	1980	MARV	2 (50%)	Smith et al. (1982)	Unknown origin; index case infected in western Kenya died, but physician secondarily infected survived
Kenya	1987	MARV	1 (100%)	Johnson et al. (1996)	Unknown origin; expatriate traveling in western Kenya
USA	1989/90	REBOV	4 (0%)	Jahrling et al. (1990)	Introduction of virus with imported monkeys from the Philippines; four humans asymptomatically infected
Italy	1992	REBOV	0 (0%)	World Health Organization (1992)	Introduction of virus with imported monkeys from the Philippines; no human infections associated
Ivory Coast	1994	CIEBOV	1 (0%)	LeGuenno et al. (1995)	Contact with chimpanzees; single case
Gabon	1994	ZEBOV	Unknown	Georges et al. (1999)	Several laboratory confirmed cases; outbreak associated with the death of nonhuman primates
Kikwit, Democratic Republic of the Congo	1995	ZEBOV	315 (77%)	World Health Organization (1995a)	Unknown origin; course of outbreak as in 1976
Gabon	1996	ZEBOV	50 (50%)	Georges et al. (1999)	Outbreak was linked to the butchering, transport and preparation for consumption of a dead chimpanzee
USA	1996	REBOV	0 (0%)	Rollin et al. (1999)	Introduction of virus with imported monkeys from the Philippines; no human infections associated
Gabon	1996/97	ZEBOV	60 (75%)	Georges et al. (1999)	Outbreak associated with the death of nonhuman primates
South Africa	1996	ZEBOV	2 (50%)	Richards et al. (2000)	Disease was introduced from Gabon
Northern Democratic Republic of the Congo	1998–2000	MARV	>100 (70%)	Bausch et al. (2003)	Outbreak with several introductions; cases are associated with illegal gold mining
Uganda	2000/01	SEBOV	425 (53%)	World Health Organization (2001)	Unknown origin; ongoing outbreak around Gulu close to the border to the Democratic Republic of the Congo
Congo-Brazaville	2002	Ebola	>100 (90%)		Originating from large outbreak among gorillas and chimpanzees

a) Numbers include a primary case that has been diagnosed some years after the epidemic (Slenczka et al. unpublished data).

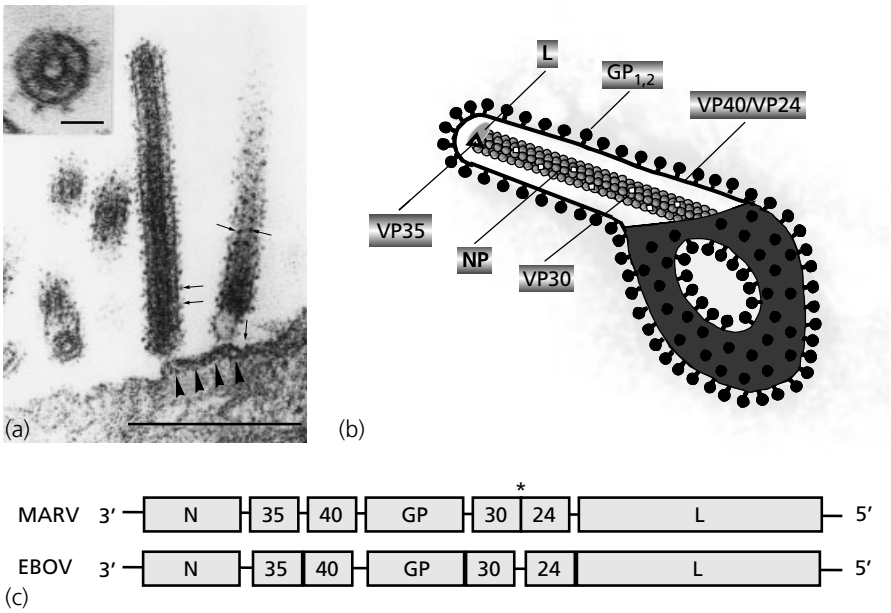

Figure 1 *Structure of filovirus particles.* **(a)** *Ultrathin sections obtained from primary cultures of human endothelial cells 3 days after infection with MARV analyzed by transmission electron microscopy. Particles consist of a nucleocapsid surrounded by a membrane in which spikes are inserted (arrows). The nucleocapsid contains a central channel (inset). The plasma membrane of infected cells is often thickened at locations where budding occurs (arrowheads) (bar, 0.5 μm; bar inset, 50 nm).* **(b)** *Schematic illustration of a filoviral particle. Four proteins are involved in nucleocapsid formation: polymerase or large (L) protein, nucleoprotein (NP), virion structural protein (VP) 30 and VP35. The glycoprotein ($GP_{1,2}$) is a type 1 transmembrane protein and anchored with the carboxy-terminal part in the virion membrane. Homotrimers of GP form the spikes on the virion surface (arrows in panel a). VP40 and VP24 are membrane-associated.* **(c)** *Schematic illustration of the filoviral genome. The genome consists of a single, negative-stranded, linear RNA molecule. G, glycoprotein gene; L, polymerase (L) gene; N, nucleoprotein gene; 24/30/35/40, virion structural protein (VP) genes; asterisk, gene overlap (altered from Feldmann and Kiley, 1999).*

membrane. Virus particles have a molecular weight of 3–6 × 10^8 and a density in potassium tartrate of 1.14 g/cm^3 (Kiley et al. 1988).

Genome structure and function

Genomes of filoviruses consist of a single negative-stranded linear RNA molecule (Kiley et al. 1982; Regnery et al. 1980). The RNA is non-infectious, does not contain a poly(A) tail, and upon entry into the cytoplasm of host cells is transcribed to generate polyadenylated subgenomic mRNA species (Kiley et al. 1982; Feldmann et al. 1992; Sanchez et al. 1993). The complete nucleic acid sequences of two different isolates of MARV (Feldmann et al. 1992; Bukreyev et al. 1995), the Mayinga isolate of ZEBOV and two isolates of REBOV (Sanchez et al. 1993; Volchkov et al. 1999, 2000a) have been elucidated. Filovirus genomes are approximately 19 kb long (MARV, 19.1 kb; EBOV, 18.9 kb) and are significantly larger than those of other *Mononegavirales*. Genes have been delineated by transcriptional signals at their 3′ and 5′ ends that have been identified by their conservation and by analysis of mRNA sequences. The following order is characteristic for filoviruses: 3′-(leader)-N-VP35–VP40–GP–VP30–VP24-L-(trailer)-5′ (Figure 1c).

Genes of filoviruses are usually separated from one another by intergenic regions that vary in length and nucleotide composition. However, some genes overlap, especially those of EBOV, and the positions and numbers of overlaps vary among filoviruses. ZEBOV possesses three overlaps, between the VP35 and VP40, GP and VP30, and VP24 and L genes, whereas MARV isolates have only one overlap, involving the VP30 and VP24 genes (Figure 1c). The length of the overlaps is centered on five highly conserved nucleotides within the transcriptional signals (3′-UAAUU-5′) that are found at the internal ends of the conserved sequences. Transcriptional start signals are conserved among filoviruses, and the sequence 3′-CUNCNUNUAAUU-5′ represents the consensus motif. Transcriptional stop signals are identical for all genes (3′-UAAUUCUUUUU-5′) except the *VP40* gene of MARV (Feldmann et al. 1992) and the *L* gene of ZEBOV (Volchkov et al. 1999) (see Figure 3). Most genes tend to possess long noncoding sequences at their 3′ and/or 5′ ends which contribute to the increased length of the genome. Extragenic sequences are found at the 3′ (leader) and 5′ (trailer) ends of the genome. Those leader and trailer sequences are complementary to one another at the extreme ends (Kiley et al. 1986; Feldmann et al. 1992; Feldman and Kiley 1999; Volchkov et al. 1999), a feature that is shared by all NNS RNA viruses.

Polypeptides

NUCLEOPROTEIN

The nucleoprotein (NP) is encoded by the 3′-most end of the linear RNA genome. The NP from various filoviruses differ slightly in their electrophoretic mobility patterns, ranging from 95 kDa (MARV) to 105 kDa (ZEBOV). The molecular weight calculated from the deduced amino acid sequences of the corresponding genes of MARV (695 amino acids) and EBOV (739 amino acids) are 78 kDa and 83 kDa, respectively, and the differences in their lengths is related to the variable C termini of the protein (Sanchez and Kiley 1989; Sanchez et al. 1992). The NP proteins possess an unusually high molecular weight compared to other NNS virus nucleocapsid proteins which range from 42 to 62 kDa. The NP protein is the major structural phosphoprotein, and only the phosphorylated form of the protein is incorporated into virions. This implies that phosphorylation is needed to form stable virion RNP complexes (Elliott et al. 1985; Elliott et al. 1993b; Becker et al. 1994). NP is the major component of the RNP complex and is tightly bound to it (see Figure 1b).

VP35: POLYMERASE COFACTOR (PHOSPHOPROTEIN EQUIVALENT)

The *VP35* gene encodes a protein that ranges from 329 amino acids for MARV to 340 for ZEBOV (Feldmann et al. 1992; Bukreyev et al. 1993; Sanchez et al. 1993). The association of this protein in the RNP complex is much weaker than that of the NP and VP30 (Elliott et al. 1985; Kiley et al. 1988). Within the complex VP35 interacts with NP and L (see Figure 1b) and the three proteins seem to be the key component of the transcription and replication machinery (Becker et al. 1998). Hydropathy plots of MARV and EBOV VP35 showed similar profiles and a prominent common hydrophilic domain in close proximity to the N-termini. This region may be involved in template binding. Data obtained with an artificial replication system revealed that VP35 is functionally equivalent to a phosphoprotein of *Mononegavirales* (Mühlberger et al. 1998, 1999). In contrast to other phosphoproteins of paramyxoviruses and rhabdoviruses, however, this protein is only weakly phophorylated (Becker and Mühlberger 1999). Finally, VP35 has been shown to function as a type I interferon antagonist (Basler et al. 2000) by interfering with IRF3 phosphorylation (Basler et al. 2003).

VP40: MATRIX PROTEIN

The VP40 of filoviruses is 303 and 326 amino acids long for MARV and ZEBOV, respectively (Feldmann et al. 1992; Sanchez et al. 1993; Bukreyev et al. 1993). This protein, which is abundant in virion particles, is not associated with the RNP complex and behaves like a membrane-associated protein when analyzed after nonionic detergent treatment of virion particles (Elliott et al. 1985; Kiley et al. 1988). VP40 is nonglycosylated, shows a predominantly hydrophobic profile, and functions as the matrix protein (see Figure 1b). VP40 is essential for assembly, and its crystal structure shows that it is composed of two structurally similar β-sandwich domains (Dessen et al. 2000; Ruigrok et al. 2000). The monomeric form of VP40 can be induced to change its conformation into oligomeric ring-like structures, which may play an important role in virus assembly and budding (Scianimanico et al. 2000). VP40 octamers have specific RNA-binding properties suggesting that this protein has additional functions in the life cycle besides promoting virion formation (Gomis Rüth et al. 2003).

GLYCOPROTEIN

The glycoprotein (GP) is encoded in the fourth gene, and is the only glycosylated structural protein of virions (Figure 1b). GP of MARV and ZEBOV are 681 and 676 amino acids in length, respectively (Will et al. 1993; Sanchez et al. 1993; Volchkov et al. 1995). They are type I transmembrane proteins and can be subdivided into a large ectodomain, a lipid membrane spanning domain of approximately 30 amino acids, and a short cytoplasmic tail of four (EBOV) and eight amino acids (MARV). GP undergoes a complex sequence of processing events in the endoplasmic reticulum (ER). This includes the removal of the signal peptide (Will et al. 1993; Sanchez et al. 1998b), *N*-glycosylation (Feldmann et al. 1991, 1994; Becker et al. 1996; Sanchez et al. 1998b), and oligomerization (Feldmann et al. 1991; Sanchez et al. 1998b). ER processing is followed by acylation in a pre-Golgi compartment (Funke et al. 1995; Ito et al. 2001), and by *O*-glycosylation and maturation of *N*-glycans in the Golgi apparatus (Feldmann et al. 1991, 1994; Geyer et al. 1992; Will et al. 1993; Becker et al. 1996). Depending on the host cell, there are wide variations in the amount of neuraminic acid present on MARV GP (Feldmann et al. 1994). Finally, GP is proteolytically cleaved into a larger amino (GP_1) and smaller carboxy-terminal (GP_2) subunit in the trans-Golgi network by a subtilisin-like proprotein convertase, most likely furin (Volchkov et al. 1998a, 2000b) (see Figure 2).

The mature envelope glycoprotein ($GP_{1,2}$) is able to form spikes on membrane surfaces without the need of other viral proteins in this maturation process (Volchkov et al. 1998b). It is anchored in the membrane via a carboxy-terminal hydrophobic domain of GP_2. The middle region of $GP_{1,2}$ is variable, extremely hydrophilic, and carries the bulk of *N*- and *O*-glycans that account for more than one-third of the molecular weight of the mature protein (Geyer et al. 1992; Will et al. 1993; Feldmann et al. 1991; Becker et al. 1996). Oligosaccharide side chains differ in their terminal sialylation patterns, which seem to be isolate-, as well as cell line-dependent (Feldmann et al. 1994). Detailed structural analyses of carbohydrates are available for MARV only

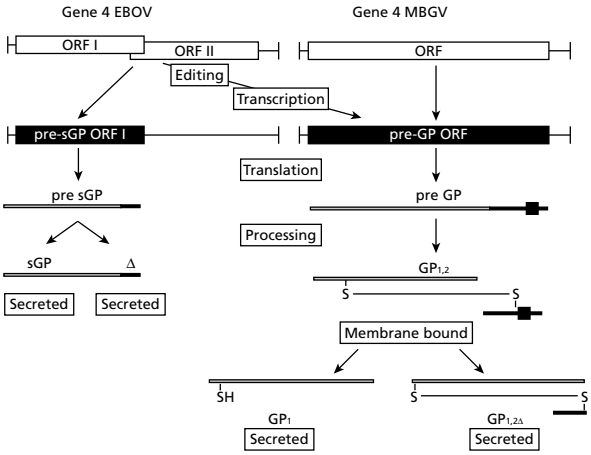

Figure 2 *Transcription and expression strategies of the glycoprotein genes of filoviruses. In contrast to MARV, the EBOV surface glycoprotein GP is encoded in two overlapping reading frames (ORF I and II), and expression of GP occurs through transcriptional editing. ORF I encodes for the precursor of the secreted small glycoprotein (pre-sGP) that is expressed from unedited transcripts and post-translationally cleaved into the soluble products sGP and Δ-peptide. Mature GP ($GP_{1,2}$) consists of the disulfide-linked (S–S) subunits GP_1 and GP_2. Significant amounts of GP_1, sGP_1, Δ-peptide, and $GP_{1,2\Delta}$ are released from cells, in soluble form (altered from Klenk et al. 1998).*

(Geyer et al. 1992). Comparison of amino acid sequences shows conservation at the amino- and carboxy-terminal ends in which the two hydrophobic domains (signal peptide, membrane anchor) and most of the highly conserved cysteine residues are located. The two most carboxy-terminal cysteine residues seem to be acylated (Funke et al. 1995; Ito et al. 2001). GP_2 contains a sequence of several uncharged and hydrophobic amino acids at a distance of 22 (EBOV) or 91 (MARV) amino acids from the cleavage site which bears some structural similarity to the fusion peptides of retroviruses (Gallaher 1996; Volchkov et al. 2000b). The special arrangement of the cysteine residues in the molecule allows an intramolecular disulfide bridge formation between the two cleavage products which results in a stem region consisting of GP_1 and GP_2 and a crownlike domain on the top formed by GP_1 carrying the mass of the carbohydrate side chains (Jeffers et al. 2002). Mature $GP_{1,2}$ is a trimer consisting of disulfide-bonded $GP_{1,2}$ molecules (Feldmann et al. 1991; Sanchez et al. 1998b). X-ray crystallography demonstrated that the central structural feature of the GP_2 ectodomain is a long triple-stranded coiled coil followed by a disulfide-bonded loop which reverses the chain direction and connects to an α helix packed antiparallel to the core helices (Weissenhorn et al. 1998a, 1998b; Malashkevich et al. 1999). During maturation GP_1 is partly shed in monomeric form after release of its disulfide linkage to the transmembrane subunit GP_2 (Volchkov et al. 1998b). Cleavage by the metalloprotease TACE results in shedding of the entire ectodomain ($GP_{1,2\Delta}$) (Dolnik et al. 2004).

In general, filovirus GPs lack significant homologies with envelope proteins of other viruses. However, a region of 26 amino acids (and less conserved surrounding sequences) in the external domain in close proximity to the transmembrane region shows significant homology to an immunosuppressive domain in envelope proteins of several retroviruses (Volchkov et al. 1992; Will et al. 1993; Bukreyev et al. 1995). This region is also the most conserved sequence in the GPs of MARV and EBOV. It is not known whether this sequence in filovirus GPs has immunosuppressive properties. As the only surface protein of virions GP functions in receptor binding and fusion (see Virus entry). Furthermore, GP is discussed (see Immune responses) as an important target for the host immune response.

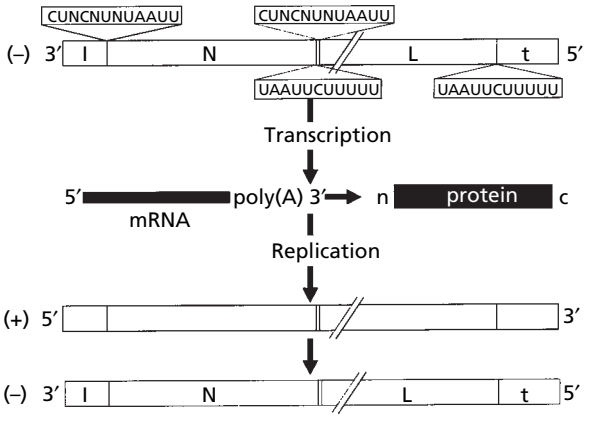

Figure 3 *The mode of transcription and replication of filoviruses, based on the data available to date. Each gene on the linear arranged nonsegmented (–)-sense genome is flanked by conserved transcriptional start (3′-CUNCNUNUAAUU-5′; indicated above) and termination signals (3′-UAAUUCUUUUU-5′; indicated underneath). Transcription starts at the 3′ end of the (–)-sense genome and leads to polyadenylated mRNA species. For replication a full-length (+)-sense antigenome is synthesized which serves as the template for the synthesis of progeny (–)-sense RNA. c, carboxy-terminal end of proteins; l, 3′ untranslated region (leader); L, viral RNA-dependent RNA polymerase; n, amino-terminal end of proteins; N, nucleoprotein; poly(A), polyadenylation of mRNA species; t, 5′ untranslated region (trailer).*

VP30: MINOR NUCLEOPROTEIN

The fifth gene encodes VP30, a protein intimately associated with the RNP complex (Elliott et al. 1985; Kiley et al. 1988) (Figure 1b). The protein has a length of 260 and 281 amino acids with ZEBOV and MARV, respectively (Feldmann et al. 1992; Sanchez et al. 1993). VP30 is the second strongest phosphorylated protein of virions (Elliott et al. 1985, 1993b; Becker and Mühlberger 1999). Using an artificial reverse genetic system (Mühlberger et al. 1999), it was shown that VP30 is essential for EBOV-specific transcription, but not replication. VP30 seems to be involved in transcription

initiation, most likely by inhibiting pausing of the transcription complex at the RNA structure of the first transcription start site. For transcription of the following genes VP30 seems to be nonessential (Weik et al. 2002).

VP24: MEMBRANE-ASSOCIATED PROTEIN OF UNKNOWN FUNCTION

VP24 is expressed from the sixth gene, and is 253 and 251 amino acids long in MARV and ZEBOV, respectively (Feldmann et al. 1992; Sanchez et al. 1993). Unlike VP40, VP24 is not completely removed from the RNP complex under isotonic conditions (Elliott et al. 1985; Kiley et al. 1988). VP24 presumably serves as a second matrix protein (see Figure 1b).

LARGE PROTEIN (RNA-DEPENDENT RNA POLYMERASE)

The large (L) protein is encoded at the 5′ end of the linear genome and has a predicted molecular weight of 267 kDa (2 331 amino acids) for MARV (Mühlberger et al. 1992) and 253 kDa (2 212) for ZEBOV (Volchkov et al. 1999). Computer-assisted comparison revealed significant homologies to L proteins of other NNS RNA viruses. Homologies are mainly located in the amino-terminal half of the protein and concentrated within three common motifs, named boxes A, B, and C. Other common features are a high content of leucine and isoleucine residues, a large positive net charge, clusters of basic amino acids interspersed with nonbasic ones, putative ATP-binding sites, two neighboring cysteine residues located in the C-terminal half of the protein, and the genome localization of the encoding gene. A highly conserved peptide motif, -GDNQ-, is located at the carboxy-terminal end of domain B and is flanked by hydrophobic amino acid residues. Similar motifs with alterations in the first amino acid have been described and discussed as catalytic sites for some RNA-dependent RNA polymerases of plant, animal, and bacterial viruses. Studies using an artificial reverse genetic system (Mühlberger et al. 1998, 1999) identified the L protein as the viral RNA-dependent RNA polymerase (see Figure 1b).

NONSTRUCTURAL GLYCOPROTEINS

The secreted glycoprotein precursor (pre-sGP) is the primary expression product of gene 4 of EBOV (Volchkov et al. 1995; Sanchez et al. 1996). For ZEBOV it has a length of 364 amino acids and shares the amino-terminal 294 amino acids with the transmembrane GP. The different carboxy terminus (69 amino acids) contains many charged residues, as well as conserved cysteine residues. sGP undergoes several co- and post-translational processing events, such as signal peptide cleavage, glycosylation, oligomerization, and proteolytic cleavage. The limiting step during maturation and transport seems to be oligomerization in the ER (Volchkova et al. 1998, 1999). After oligomerization sGP is transported into the Golgi compartments where glycosylation is completed and posttranslational cleavage by furin into the mature form sGP and a small peptide, called Δ-peptide, occurs (Volchkova et al. 1999). Due to the lack of a transmembrane anchor mature sGP is efficiently secreted from infected cells, a process which is independent of proteolytic cleavage. sGP appears as a disulfide-linked homodimer which shows an antiparallel orientation (Sanchez et al. 1998b; Volchkova et al. 1998). Dimerization is due to an intermolecular disulfide linkage between the amino and carboxy-terminal cysteine residues at positions 53 and 306, respectively. The remaining four highly conserved cysteine residues at the amino-terminus seem to be involved in the intramolecular folding of monomers (Volchkova et al. 1998).

Δ-peptide, the small cleavage product of pre-sGP, varies in length between 40 and 48 amino acids for the different EBOV. Its molecular mass of approximately 10 to 14 kDa is significantly larger than the one predicted from the amino acid sequence (approximately 4.7 kDa). The difference is due to the attachment of several *O*-glycans that carry terminal sialic acids. In this respect it differs from sGP which seems to mainly carry *N*-linked carbohydrates. As with mature sGP the peptide is secreted from infected cells (Volchkova et al. 1999).

The small secreted glycoprotein (ssGP) of EBOV resembles a natural carboxy-terminal truncated variant of sGP and is generated from gene 4 by transcriptional editing. Due to the lack of a transmembrane anchor and carboxy-terminal cysteine residues ssGP is secreted in monomeric form (Volchkov et al. 1995; Volchkova et al. 1998).

FILOVIRUS REPLICATION

Virus growth in cell cultures

The Vero cell line, especially the E6 clone, is most widely used for virus isolation and propagation. Primary virus isolation has also been successful in MA-104 and SW13 cells (McCormick et al. 1983; Jahrling et al. 1990). A variety of other cells have been tested as substrates for filovirus replication (van der Groen et al. 1978; McCormick et al. 1983; Peters et al. 1992). These include human microvascular endothelial cells (HMEC-1), primary cultures of human umbilical cord vein endothelial cells (HUVEC), and human peripheral blood monocytes/macrophages (Schnittler et al. 1993; Feldmann et al. 1996a).

MARV and ZEBOV cause lytic infections in cell culture. SEBOV and REBOV replicate more slowly upon primary isolation, and the cytopathic effect (CPE) is not as prominent as with ZEBOV. The course of infection in tissue culture can be monitored by an indirect immunofluorescence assay (IFA) or by plaque assay. In cases of little or no CPE, reverse transcriptase-polymerase chain reaction (RT-PCR) on viral RNA isolated from infected cells and tissue culture

supernatants can be helpful for quantification (Schnittler et al. 1993; Sanchez and Feldmann 1996).

Viral subgenomic RNA synthesis in tissue culture is detectable as early as 3 h after infection, reaches a maximum by 18 h, and declines thereafter. CPE is not seen before 48 h after infection. The first subgenomic RNA to be detected is NP-specific which reaches levels sufficient to produce protein by 7 h after infection. All proteins are detectable by in vitro translation of polyadenylated RNA isolated 18 h after infection, thereafter the yield of translation products decreases. Polymerase chain reaction (PCR) assays of genomic RNA of MARV particles in supernatants of infected cells indicated that the replication cycle is approximately 12 h (Sanchez and Kiley 1987; Schnittler et al. 1993; Mühlberger et al. 1996).

Virus entry

The filovirus GP mediates receptor binding and subsequent fusion with susceptible cells (Takada et al. 1997; Wool-Levis and Bates 1998; Yang et al. 1998; Chan et al. 2000b). There is evidence that MARV uses the asialo glycoprotein receptor to infect hepatocytes (Becker et al. 1995). For EBOV, it was suggested that integrins, especially the beta 1 group, might interact with the glycoprotein and perhaps be involved in virus entry (Takada et al. 2000). Other studies indicate that the folate receptor alpha serves as cofactor for entry of EBOV and MARV (Chan et al. 2001). A similar role has been postulated for C-type lectins (Alvarez et al. 2002). Fusion activity has never been experimentally demonstrated using standard methodology. Early post-infection filovirus particles are associated with coated pits along the plasma membrane indicating endocytosis as a possible mechanism for entry (Geisbert and Jahrling 1995). This is supported by studies which employed lysosomotropic agents (Mariyankova et al. 1993; Chan et al. 2000b). A fusion peptide was postulated for ZEBOV in a distance of 22 amino acids from the cleavage site (amino acids 524–539) (Gallaher 1996). Recently it was demonstrated that the same peptide induces fusion with liposomes (Ruiz-Argüello et al. 1998). This together with mutational analysis of the putative fusion domain (Ito et al. 1999) offers compelling support for a fusion peptide role for this conserved hydrophobic region in the EBOV GP. For MARV a similar putative fusion domain can be found at a distance of 91 amino acids from the cleavage site (Volchkov et al. 2000b). Receptor binding and fusion are followed by uncoating, a mechanism which is unknown.

Transcription, translation, and genome replication

Filovirus transcription and replication take place in the cytoplasm of infected cells, and the mechanisms resemble those of other NNS RNA viruses. As with other members of the order *Mononegavirales*, transcription is believed to start at the extreme 3′ end, leading to the synthesis of a short (+)-leader sequence that is terminated when the first transcription start site is encountered (Figure 3). The seven structural genes are subsequently transcribed to produce seven monocistronic polyadenylated subgenomic RNA species. There is no evidence for larger amounts of bi- or multicistronic subgenomic RNA species (Sanchez and Kiley 1987; Feldmann et al. 1992; Sanchez et al. 1993). Analyses of MARV mRNA species have shown that the 5′ ends of the transcripts are two bases shorter than previously published (Mühlberger et al. 1996). All start signals of filovirus genes contain the consensus sequence 3′-CUNCNUNUAAUU-5′. The 3′ ends of the transcripts carry a poly(A) tail generated by a stuttering mechanism of the viral polymerase at a run of five to six uridine residues located at the 5′ end of all transcription stop signals. Therefore, the sequence 3′-UAAUU-CUUUUU(U)-5′ serves as a transcription stop and polyadenylation signal. Both signals carry the pentamer 3′-UAAUU-5′, a unique feature among NNS RNA viruses. The function of the pentamer is unknown, but it could serve as the recognition site for positioning the polymerase complex. The surrounding semiconserved sequences may then mediate the exact initiation of transcription and termination/polyadenylation events.

Filovirus transcripts start precisely at the first nucleotide of the highly conserved transcriptional start signal. They contain unusually long untranslated regions especially at the 3′ ends. The 5′ end untranslated regions can build a stable secondary structure with the conserved nucleotides located in the stem region of a hairpin. Nucleotide substitutions in the conserved 5′ regions are accompanied by compensatory mutations of the complementary nucleotide thus leading to conservation of the secondary structure. Hairpin formation might play a role in transcript stability and ribosome binding (Sanchez et al. 1993; Mühlberger et al. 1996). The role of gene overlaps in regulation of transcription is unknown. Sanchez et al. (1993) proposed that, following mRNA synthesis, transcription is reinitiated by reposition of the polymerase at the downstream start site. This ‘back up’ mechanism is supported by the finding that attenuation of filovirus genes with start sites in overlaps does not occur to any higher degree, as has been noted for a much larger overlap found in the respiratory syncytial virus genome. Alternatively, the polymerase may occasionally terminate transcription without polyadenylation at the overlap and initiate transcription of the downstream gene, but there is no evidence for detectable levels of transcripts lacking poly(A) tails (see Figure 3).

The switch mechanism between transcription and replication is unknown, but as with other NNS viruses, synthesis of the NP protein could be a key factor.

Encapsidation and polymerase complex entry sites are probably located on the leader sequence, and the fact that the ends of the genome are complementary suggests a single identical encapsidation site on genome and antigenome. This would function for both transcription as well as replication (Feldmann et al. 1992). Replication involves a full-length (+)-strand antigenome which serves as the template for synthesis of (−)-strand genome molecules. Encapsidated genomic RNA forms nucleocapsids that go into the formation of new infectious virions at the cell surface (Figure 3).

In the past years artificial replication systems have been developed for MARV and EBOV which allowed more detailed study of the requirements for transcription and replication (Mühlberger et al. 1998, 1999). It could be demonstrated that NP, VP35, and L are essential and sufficient for transcription, as well as replication and encapsidation of MARV monocistronic monigenomes, whereas EBOV-specific transcription was also dependent on the presence of VP30 systems (see Polypeptides). Recently, the successful generation of infectious clones for ZEBOV was reported which will finally allow the determination of the critical steps in virus replication (Volchkov et al. 2001; Neumann et al. 2002).

The organization and transcription of the GP genes of EBOV is unusual, and involves transcriptional editing. EBOV GP genes possess two overlapping reading frames (Figure 2). Full-length GP is expressed by the addition of a single nontemplated adenosine residue at a run of seven uridine residues on the vRNA template (Volchkov et al. 1995; Sanchez et al. 1996). The primary gene product is a small nonstructural glycoprotein (sGP) that is secreted from infected cells (see Nonstructural glycoproteins). In addition, virus variants have been found after passaging in tissue culture and animals that express full-length GP from a single open reading frame. Those variants acquired a mutation that added a single uridine nucleotide at the editing site connecting the GP open reading frame (Sanchez et al. 1993; Volchkov et al. 1995). The MARV GP is expressed in a single frame and the gene does not contain sequences favoring mechanisms such as editing or frameshifting (Will et al. 1993; Bukreyev et al. 1995).

Virus assembly and exit

Virions usually bud at the plasma membrane, and the budding process is probably mediated at membrane locations where GP is incorporated. The cytoplasmic tail of GP is thought to interact with VP40 or VP24, or both. VP40 or VP24 may mediate the linkage between the RNP complexes and the transmembrane protein GP (see also Polypeptides). Particles mature preferentially in a vertical mode, but budding via the longitudinal axis has also been observed. In macrophages, budding has also been observed at intracytoplasmic membranes surrounding vacuoles which form during infection (Feldmann et al. 1996a). VP40 appears to be targeted by 'late domains' to multivesicular bodies that may play an important role in virus assembly (Kolesnikova et al. 2002; Jasenosky and Kawaoka 2004).

CLINICAL AND PATHOLOGICAL ASPECTS

Epidemiology

It is generally accepted that human filovirus outbreaks are of a zoonotic nature. Guinea pigs, primates, bats, and hard ticks have been suspected to be natural hosts, but the search for filoviruses in these and many other wild species was unsuccessful. Studies on experimentally infected wild animals have shown that fruit and insectivorous bats support replication and circulation of high titers of EBOV without necessarily becoming ill, indicating that bats could serve as the reservoir host (Swanepoel et al. 1996).

MARV and the SEBOV and ZEBOV appear to be indigenous to the African continent, and both EBOV species have been isolated from human patients only in Africa. MARV has been isolated from human patients in Africa and Europe, though the European cases were caused by a virus originating from Africa (Martini and Siegert 1971). The REBOV outbreak provided the first evidence for the presence of a filovirus outside Africa (Hayes et al. 1992). Serological studies (IFA) among captive macaques in the Philippines indicated that the source of REBOV might be wild nonhuman primates. However, IFA-detected antibodies seem to be spurious, and latent infections in nonhuman primates have never been observed (Fisher-Hoch et al. 1992).

Serological studies suggest that filoviruses are endemic in many central African regions (summarized in Feldmann et al. 1996b, 2003). Serosurveys in other countries, such as Germany, the United States, and the Philippines, have identified antibodies to filoviruses in humans as well. Serological data based on IFA are of only limited reliability, as nonspecific reactivity has been observed when filovirus antigens are used. Nevertheless, it is possible that subclinical infections caused by known or unknown filoviruses or a closely related virus (paramyxovirus?) may be responsible for a certain amount of the seropositivity detected in human populations.

Clinical manifestation

MODE OF TRANSMISSION

Person-to-person transmission by intimate contact is the main route of infection in human outbreaks. The EBOV

outbreaks in 1976 and 1995 and the MARV outbreak in 1967 all involved nosocomial transmission via contaminated syringes and needles. Therefore, extreme care should be taken with blood, secretions, and excretions from infected patients. On the basis of experiences from these episodes, isolation of patients, use of strict barrier nursing procedures (e.g. protective clothing, respirator), and measures to handle and disinfect contaminated material promptly are sufficient to prevent transmission to healthcare workers. Transmission by droplets and small-particle aerosols have been observed in outbreaks among experimentally infected and quarantined imported monkeys. This is confirmed by identification of filovirus particles in alveoli of naturally and experimentally infected monkeys and humans (Peters et al. 1991; Pokhodyaeu et al. 1991; Geisbert et al. 1992; Zaki and Peters 1997; Zaki and Goldsmith 1999). Epidemiological studies of human outbreaks, however, indicate that aerosols and droplets do not seem to be an important route of transmission.

CLINICAL SYNDROME

The onset of the disease is sudden with fever, chills, headache, myalgia, and anorexia. This may be followed by symptoms such as abdominal pain, sore throat, nausea, vomiting, cough, arthralgia, diarrhea, and pharyngeal and conjunctival injection (Figure 4). Patients are dehydrated, apathetic, disoriented, and may develop a characteristic, nonpuritic, maculopapular centripetal rash associated with varying degrees of erythema and desquamate by day 5–7 of the illness. Hemorrhagic manifestations develop during the peak of the illness; they are of prognostic value for the disease. Bleeding into the gastrointestinal tract is most prominent beside petechia and hemorrhages from puncture wounds and mucous membranes. Laboratory parameters are less characteristic, but the following findings are associated with the disease: leukopenia (as low as 1 000/μl), left shift with atypical lymphocytes, thrombocytopenia (50 000–100 000/μl), markedly elevated serum transaminase levels (AST typically exceeding ALT), hyperproteinemia, and proteinuria. Prothrombin and partial thromboplastin times are prolonged and fibrin split products are detectable. In a later stage, secondary bacterial infection may lead to elevated white blood counts.

Nonfatal cases have fever for about 5–9 days; fatal cases develop clinical signs early during infection and death commonly occurs between day 6 and 16, due to hemorrhage and hypovolemic shock. Mortality is high and varies between 22 and 88 percent depending on the virus. The highest rate has been reported for ZEBOV; REBOV seems to possess a very low pathogenicity for humans or may even be apathogenic.

Convalescence is prolonged and sometimes associated with myelitis, recurrent hepatitis, psychosis, or uveitis. There is an increased risk of abortion for pregnant women, and clinical observations indicate a high death rate for children of infected mothers (Martini and Siegert 1971; Pattyn 1978; Baron et al. 1983; Peters et al. 1996; Peters and LeDuc 1999; Sanchez et al. 2001).

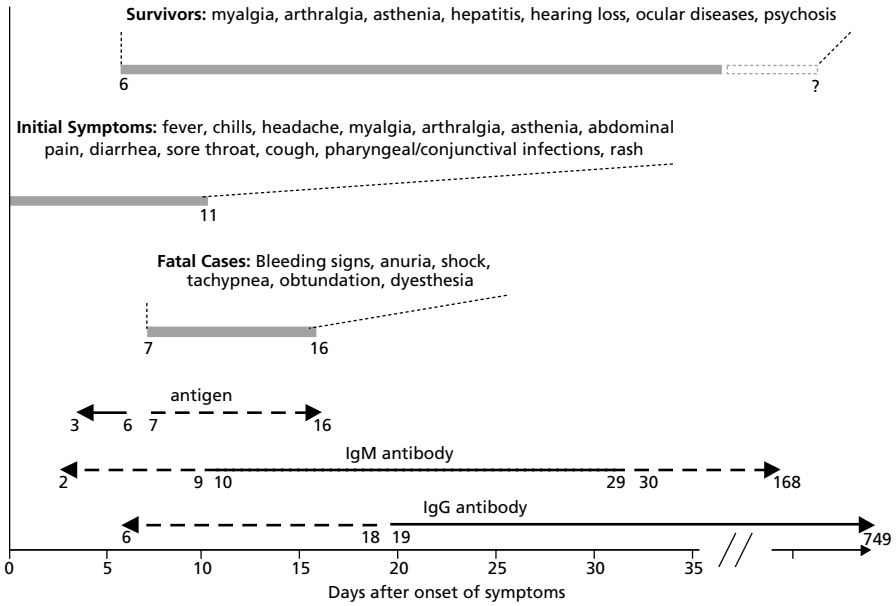

Figure 4 *Clinical course of filoviral hemorrhagic fever. The scheme presents an average clinical course of Ebola hemorrhagic fever. Key: gray bars, time interval of symptoms; black lines, period in which clinical samples are most likely be tested positive (antigen, IgM, or IgG antibodies); dashed lines, period in which a mix of positive and negative results can be obtained (antigen, IgM or IgG antibodies); numbers, days post onset of symptoms (adapted from Bwaka et al. (1999) and Rowe et al. (1999)).*

Pathology

PATHOLOGY IN EXPERIMENTAL ANIMALS

Monkeys, guinea pigs, suckling mice, and hamsters have been experimentally infected with filoviruses. MARV and ZEBOV are highly virulent for most of these species. SEBOV and REBOV are less virulent, often causing a self-limited infection in guinea pigs and monkeys.

The incubation period for rhesus and African green monkeys inoculated with MARV and ZEBOV is 4–16 days. High titers of virus can be detected in liver, spleen, lymph nodes, and lungs by onset of clinical symptoms. All these organs, especially liver, show severe necrosis due to virus replication in parenchymal cells. Little inflammatory response at those sites is typical. Interstitial hemorrhage occurs and is most prominent in the gastrointestinal tract. In infected nonhuman primates, thrombocytopenia has been found accompanied by aggregation disorders of the remaining platelets in response to agonists such as ADP and collagen (Murphy et al. 1971; Fisher-Hoch et al. 1985). Histopathological damage of the target organs is at odds with serum transferase levels showing increases in AST and ALT (AST:ALT = 7:1). This argues against hepatocellular dysfunction and raises the question for extrahepatic targets (Peters et al. 1996). Morphologic studies on REBOV-infected monkeys revealed extensive virus replication in tissue macrophages, interstitial fibroblasts of many organs, circulating monocytes/macrophages and less frequently in endothelial cells, hepatocytes, adrenal corticoid cells, and renal tubular epithelium (Geisbert et al. 1992). Similar results have been reported from monkeys experimentally infected with MARV and ZEBOV (Ryabchikova et al. 1999).

PATHOLOGY IN HUMANS

In fatal cases, generalized hemorrhage is found macroscopically in most organ systems. Microscopic changes include focal necrosis in liver, lymphatic organs, kidneys, testes, and ovaries. The liver, although always involved with large eosinophilic intracytoplasmic inclusion bodies in hepatocytes and Councilman-like bodies within necrotic foci, is not the site of massive, potentially fatal necrosis. Generalized lymphoid necrosis is characteristic for the disease, and renal tubular necrosis is commonly found in agonal stages. A diffuse encephalitis, as described for many viral infections, has been observed. In addition, focal hemorrhages have been observed. The clotting system is activated and intravascular fibrin thrombi have been observed. Viral antigen can be detected in many organs, predominantly in liver, kidneys, spleen, and adrenal glands. Viral persistence has been demonstrated for filoviruses by antigen/RNA detection or isolation from liver biopsy material, anterior chamber of the eye (4–5 weeks), and semen (12 weeks), despite an apparently normal immune response (e.g. Martini and Siegert 1971; Pattyn 1978; Peters et al. 1996; Rowe et al. 1999; Sanchez et al. 2001).

Pathophysiology

Pathophysiological changes that make filovirus infections so devastating are only partially understood. Clinical and biochemical findings support the anatomical observations of extensive liver involvement, renal damage, changes in vascular permeability, and activation of the clotting cascade. The visceral organ necrosis is a consequence of virus replication in parenchymal cells. However, no organ, not even the liver, shows sufficient damage to account for death. The role of disseminated intravascular coagulation (DIC) in pathogenesis is still controversial, because laboratory confirmation of DIC in human infections has never been demonstrated. In nonhuman primates the intrinsic clotting pathway is most affected, whereas the extrinsic pathway is spared.

Laboratory parameters in the crucial early stage of filovirus hemorrhagic fever, such as high AST/ALT ratio, normal bilirubin levels, and marked lymphopenia followed by a dramatic neutrophilia with left shift, suggest extrahepatic targets in the infection (Peters et al. 1996). As with some hemorrhagic fever with renal syndrome, dengue hemorrhagic fever, and Lassa fever, fluid distribution problems and platelet abnormalities are dominant clinical manifestations indicating dysfunction or damage of endothelial cells and platelets. Post mortem, there is little monocyte/macrophage infiltration in sites of parenchymal necrosis suggesting that also a dysfunction of white blood cells, such as macrophages, occurs. Morphological studies on REBOV-infected monkeys from the 1989 epizootic (Geisbert et al. 1992) and monkeys experimentally infected with ZEBOV (Ryabchikova et al. 1999) showed that monocytes/macrophages and fibroblasts are the preferred sites of virus replication in early stages, whereas other cell types may become involved as the disease progresses. Human macrophages in culture are also sensitive to infection resulting in massive production of infectious virus and cell lysis (Feldmann et al. 1996a). Although the studies on infected nonhuman primates did not identify endothelial cells as sites of massive virus replication, in vitro studies and investigations on human cases with EBOV hemorrhagic fever clearly demonstrated that endothelial cells are suitable targets for virus replication (Schnittler et al. 1993). Here, infection leads to complete cell lysis indicating that damage of endothelial cells may occur during infection. Recently cell destruction upon expression of EBOV glycoprotein was reported (Chan et al. 2000a; Yang et al. 2000).

Supernatants of MARV-infected monocyte/macrophage cultures can increase paraendothelial permeability in an in vitro model (Feldmann et al. 1996a). Examina-

tion for mediators in those supernatants revealed increased levels of secreted cytokines and chemokines, especially TNF-α. These data support a mechanism of a mediator-induced vascular instability that leads to increased permeability and a shock syndrome that is seen in severe cases. Hemorrhagic manifestations, however, are also likely to be caused in part by the damage inflicted upon the reticuloendothelial system as a direct result of massive virus replication. Hemorrhages occur later in infection and could be due to an extended damage which cannot be repaired by wound-healing mechanisms. The bleeding tendency is reinforced by a decrease in blood pressure as a common consequence of shock. The combination of viral replication in endothelial cells and virus-induced cytokine release from macrophages may also promote a distinct proinflammatory endothelial phenotype that then triggers the coagulation cascade (Schnittler and Feldmann 1999).

Immune responses

The mechanisms of recovery from filovirus infections in humans and wild as well as laboratory animals are not well understood. In contrast to survivors and asymptomatic cases that show IgM and IgG antibody responses to filovirus antigens, fatal filovirus infections usually end with high viremia and little evidence of a humoral immune response (Baize et al. 1999; Ksiazek et al. 1999; Leroy et al. 2000). Neutralizing anti-GP antibodies were shown to have protective and therapeutic properties in animal models (Maruyama et al. 1999; Wilson et al. 2000). Protection by convalescence sera has been reported anecdotically, but has not been evaluated in controlled clinical trials to date (Mupapa et al. 1999).

Immunosuppression, in general, seems to be an important factor in the pathogenesis of filoviral hemorrhagic fever. The mechanisms, however, leading to the immunosuppressed status of the hosts are unknown and currently being investigated. In humans and monkeys, there is extensive disruption of the parafollicular regions in the spleen and lymph nodes, and proliferation of filoviruses in macrophages (cytolytic in vitro) has been demonstrated (Murphy et al. 1971; Baskerville et al. 1985; Geisbert et al. 1992; Feldmann et al. 1996a; Ryabchikova et al. 1999). For EBOV, it has been reported that sGP interacts with the host immune response by binding to neutrophils through CD16b, the neutrophil-specific form of the Fcγ receptor III. Subsequently, sGP binding appears to inhibit early activation of these cells (Yang et al. 1998; Kindzelskii et al. 2000). This concept, however, has been challenged by a report from Maruyama and colleagues (1998). Relatively high amounts of GP_1 are released into the medium of filovirus-infected cells, and it has been discussed that this soluble glycoprotein as well as sGP may effectively bind antibodies that might otherwise be protective (Sanchez et al. 1996; Volchkov et al. 1998b; Ito et al. 2001). In addition, filovirus transmembrane glycoprotein molecules possess a sequence close to the carboxy terminus resembling a presumptive immunosuppressive domain found in retrovirus glycoproteins (Volchkov et al. 1992; Will et al. 1993; Bukreyev et al. 1995). Peptides synthesized according to this 26 amino acid long region inhibited the blastogenesis of lymphocytes in response to mitogens, inhibited production of cytokines, and decreased proliferation of mononuclear cells in vitro (Ignatyev 1999). It is not yet known, however, if the immunosuppressive domain on the GP is functional on mature molecules.

There is also evidence that filoviruses interfere with innate immunity which is generally believed to play an important role in viral replication and which, therefore, allows the cellular and the humoral arm of the immune system to clear the virus in later stages of the infection. Recent studies with EBOV have shown that VP35 blocks dsRNA- and virus-mediated induction of an IFN-responsive promoter and the IFN-β promoter. VP35 is therefore likely to function as an inhibitor of the type I IFN response in EBOV-infected cells and may be an important determinant in EBOV pathogenicity (Basler et al. 2000).

Diagnosis

In tropical settings identification of a filovirus hemorrhagic fever may be difficult, because the most common causes of severe, acute, febrile disease are malaria and typhoid fever. A wide range of infectious disease must be considered next, such as shigellosis, meningococcal septicemia, plague, leptospirosis, anthrax, relapsing fever, typhus, murine typhus, yellow fever, Chikungunya fever, Rift Valley fever, hemorrhagic fever with renal syndrome, Crimean–Congo hemorrhagic fever, Lassa fever, and fulminant viral hepatitis. Travel, treatment in local hospitals, contact with sick persons or wild and domestic monkeys are useful historical features in returning travelers, especially from Africa. Diagnosis of single cases is extremely difficult, but the occurrence of clusters of cases with prodromal fever followed by cases of hemorrhagic diatheses and person-to-person transmission are suggestive of viral hemorrhagic fever, and containment procedures have to be initiated. In filoviral hemorrhagic fever prostration, lethargy, wasting, and diarrhea seem to be more severe than observed in patients with other viral hemorrhagic fevers. The rash is characteristic and useful in differential diagnosis.

Laboratory diagnosis can be achieved in two ways: measurement of the host-specific immune response to the infection; and detection of viral antigen and genomic RNA in the infected host (Table 2, Figure 4).
Antigen detection ELISA (Ksiazek et al. 1992, 1999) and reverse transcriptase-polymerase chain reaction (Sanchez and Feldmann 1996; Sanchez et al. 1999) are the primary tests to diagnose an acute infection. For antibody detection the most commonly used assays are

Table 2 *Laboratory diagnosis*

Test	Target	Source	Remarks
Indirect immunofluorescence assay (IFA)	Virus-specific antibodies	Serum	Simple to perform, but prone to false positives and subjective interpretation
Enzyme-linked immunosorbent assay (ELISA)	Virus-specific antibodies	Serum	Specific and sensitive, but initial response slower than IFA
Immunoblot	Virus-specific antibodies	Serum	Protein-specific, but interpretation sometimes difficult
Antigen ELISA	Viral antigen	Blood, serum, tissues	Rapid and sensitive, but requires special equipment
Immunohistochemistry	Viral antigen	Tissues (e.g. skin, liver)	Inactivated material, but requires time
Fluorescence assay (FA)	Viral antigen	Tissues (e.g. liver)	Rapid and easy, but interpretation is subjective
Polymerase chain reaction (PCR)	Viral nucleic acid	Blood, serum, tissues	Rapid and sensitive, but requires special equipment
Electron microscopy	Viral particle	Blood, tissues	Unique morphology (immunostaining possible), but insensitive and requires expensive equipment
Virus isolation	Viral particle	Blood, tissues	Virus available for studies, but requires time

A surveillance assay based on formalin-fixed skin specimens has been established for the field (Lloyd et al. 1999).

direct IgG and IgM enzyme-linked immunosorbent assays (ELISA) (Ksiazek 1991; Becker et al. 1992), and IgM capture assay (Ksiazek et al. 1999). Confirmatory tests include Western blot (Becker et al. 1992; Elliott et al. 1993a) and the indirect immunofluorescence assay on acetone-fixed infected cells inactivated by γ-radiation. Electron microscopy has been particulary useful in diagnosis of filovirus infections (Siegert et al. 1967; Murphy et al. 1978; Jahrling et al. 1990). Viral structures can be visualized in culture fluid from initial passage cell cultures by negative staining, and in thin sections of any infected material. Immunohistochemistry on formalin-fixed material and paraffin-embedded tissues can be used for detection of filoviruses (Jahrling et al. 1990), as well as immunofluorescence on impression smears of tissues (Rollin et al. 1990).

Viral antigen can be detected in blood from day 3 up to 7–16 days after the onset of symptoms. With the development of more sensitive tests, such as the direct IgG and and the IgM capture ELISA (Ksiazek et al. 1999) antibody detection became more valuble in early diagnosis. Based on data from Kikwit, IgM antibodies appear between 2 and 9 days after the onset of symptoms and disappear between 30 and 168 days after onset. IgG-specific antibodies develop between day 6 and 18 after onset and persist (Rowe et al. 1999) (Figure 4).

Attempts to isolate virus from serum or other clinical material should be performed using Vero or MA-104 cells (monkey kidney cells). However, most filoviruses do not cause extensive cytopathic effect on primary isolation. Guinea pigs can be used for primary isolation of those filoviruses that initially do not grow well in tissue culture. Several passages are usually required to produce a uniformly fatal disease.

Patient management and control

Vaccination and chemotherapy for human application do not exist yet. Supportive therapy should be directed towards maintenance of effective blood volume and electrolyte balance. Shock, cerebral edema, renal failure, coagulation disorders, and secondary bacterial infection have to be managed and may be life-saving. Heparin treatment should only be considered in cases with clear evidence for DIC. Human convalescence plasma has been used to successfully treat patients (Mupapa et al. 1999). However, its general usefulness remains unconfirmed. Recently neutralizing anti-GP antibodies could be generated from different species, including human, which were immunized or infected with EBOV. The neutralizing antibodies showed protective and therapeutic properties in animal models (Maruyama et al. 1999; Wilson et al. 2000). Filoviruses are resistant to the antiviral effects of interferon, and interferon administration to monkeys has failed to increase survival rate or achieve a reduction in virus titer. Ribavirin has no effect on filoviruses in vitro and is probably of no therapeutic value.

Isolation of patients is recommended, and protection of medical and nursing staff is required. This can be achieved by strict barrier nursing techniques and the use of high-efficiency particulate air (HEPA) filter respirators for protection against aerosols when feasible. Detailed information has been published regarding management of patients with suspected filoviral hemorrhagic fever and ways to minimize spread of virus in outbreaks, especially in Africa (Centers for Disease Control and Prevention 1988; World Health Organization 1995b).

A protective vaccine would be extremely valuable for at-risk medical personnel in Africa and researchers

working with infectious filoviruses. Crossprotection among different EBOV subtypes in experimental animal systems has been reported, suggesting a general value of vaccines (Bowen et al. 1980; Fisher-Hoch and Brammer 1992). Inactivated vaccines have been developed with formalin or heat treatment of cell culture-propagated MARV and EBOV (species Sudan and Zaire) (Lupton et al. 1980; Agafonov et al. 1992). Because of the biohazard of filoviruses and the general lack of knowledge as to the pathogenic processes involved in filovirus diseases, it would be difficult to insure the safety of attenuated strains of MARV or EBOV. The transmembrane glycoprotein GP is assumed to be the major antigenic molecule of virion particles. The successful use of this protein in different immunization approaches has clearly demonstrated its immunogenic and protective properties in small animal models and nonhuman primates (Hevey et al. 1998; Vanderzanden et al. 1998; Xu et al. 1998; Pushko et al. 2000; Sullivan et al. 2000; Sullivan et al. 2003; Garbutt et al. 2004).

The importation of wild-caught monkeys is an important factor in the introduction of filoviruses into foreign human populations (Martini and Siegert 1971; Jahrling et al. 1990; World Health Organization 1992). Quarantine of imported nonhuman primates and professional handling and testing of these animals will help to minimize the risk of filovirus outbreaks in humans. Guidelines have been published for quarantine and proper handling of monkeys in medical research (Centers for Disease Control and Prevention 1990).

Filovirus infectivity is quite stable at room temperature (20°C), but is destroyed in 30 min at 60°C. Infectivity is also destroyed by ultraviolet and γ-irradiation, formalin (1 percent), lipid solvents (deoxycholate, ether), β-propiolactone, and hypochloric and phenolic disinfectants (Elliott et al. 1982; Centers for Disease Control and Prevention 1988, 1993).

Rhabdoviruses: rabies

NOËL TORDO, PIERRE-EMMANUEL CECCALDI, YVES GAUDIN, AND ALEX I. WANDELER

Introduction	1	Clinical and pathological aspects: rabies infection	16
Properties of the viruses	1	Pathogenesis and pathology	19
Clinical and pathological aspects: vesiculovirus infection	15	References	26

INTRODUCTION

The family *Rhabdoviridae* (from Greek *rhabdos*: rod) contains hundreds of viruses whose hosts vary widely among vertebrates, invertebrates, and plants (Murphy et al. 1995; Tordo et al. 2004) in which they give rise to various diseases (Figure 1). This variability contrasts strongly with their striking similarity in morphology, structure, and mechanisms of replication. Another common feature is that all members present a danger to humans, not only from direct disease but also from livestock and crop losses.

Arthropods are their most frequent vectors and probable original reservoirs, from which they adapted to plants and vertebrates. Traces of this evolution still exist: the sigma virus exclusively infects the fruit fly *Drosophila*; the plant rhabdoviruses have mixed arthropod–plant cycles; vesiculoviruses, ephemeroviruses, and possibly lyssaviruses undergo mixed insect–mammal cycles; and some evidence even suggests that an aquatic arthropod could be involved in the transmission of fish rhabdovirus. Several insect species replicate both vertebrate and plant rhabdoviruses, but a triple insect–plant–vertebrate cycle has not so far been observed. Finally, rabies and rabies-related viruses became more narrowly adapted and now infect only mammals. The vast majority of rhabdoviruses are transmitted mechanically: in plants by injury or through arthropod or worm vectors and in vertebrates by aerosols, contact, bite, or sexual transmission. A few viruses (e.g. the sigma virus of *Drosophila*) are vertically transmitted.

For historical reasons, studies on rabies virus contributed greatly to the development of vaccines, pathology, and analysis of the immune response. Studies on vesicular stomatitis virus, which is comparatively safe to handle and replicates readily in most cell types, have provided much useful biochemical, biophysical, and molecular data. The fish, plant, and cattle rhabdoviruses, long neglected, have recently attracted increased attention because of their economic importance.

PROPERTIES OF THE VIRUSES

The *Rhabdoviridae*

The family *Rhabdoviridae* belongs to the order *Mononegavirales*, which also embraces the families *Paramyxoviridae*, *Filoviridae* and *Bornaviridae*. These viruses share a linear nonsegmented RNA genome of negative polarity embedded within a helical ribonucleoprotein complex (RNP). The criteria for *Rhabdovirus* classification have been progressively sharpened, taking into account physical, chemical, and structural properties, antigenicity and, finally, genetics. The viruses were first grouped into genera or other groups by serological cross-reactions between internal antigens and their antibodies. Subdivision into serotypes was performed by cross-reaction between envelope antigens (Schneider et al. 1973). The use of monoclonal antibodies (mAbs) further refined the classification (Rupprecht et al. 1991). Molecular biology techniques permitted phylogenetic

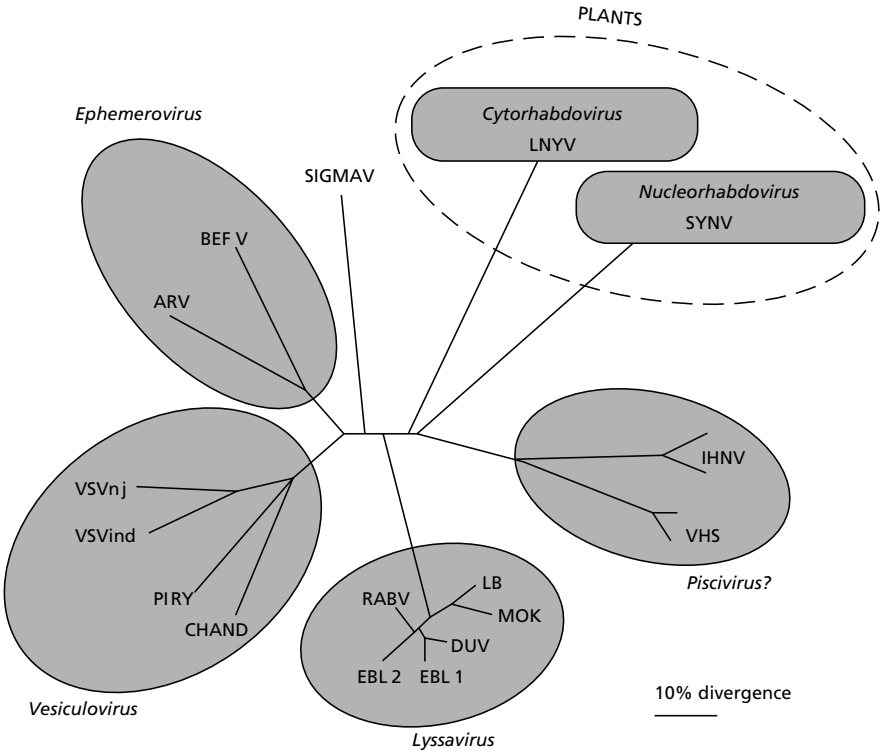

Figure 1 *Radial phylogenetic tree of the* Rhabdoviridae *family established from N protein sequence alignment using the ClustalW program (neighbor joining method). Gray circles outline the genera. studies and the definition of genotypes (Badrane et al. 2001; Bourhy et al. 1993a; Morzunov et al. 1995; Tordo et al. 1995; Wang et al. 1995; Tordo et al. 2004 and references herein). However, a considerable number of rhabdoviruses remain, classified only roughly on the basis of morphology, host or geographical distribution, or pathological features. Further analysis is needed to justify their inclusion in existing groups or the creation of new ones.

GENUS *VESICULOVIRUS*

The main member of the genus *Vesiculovirus* (Latin *vesicula*: blister) is vesicular stomatitis virus (VSV), which is frequently designated as the prototype of the entire family *Rhabdoviridae*. Eight species have been characterized, of which Indiana and New Jersey are the most recent (Murphy et al. 1995; Tordo et al. 2004). VSV causes a febrile illness in cattle, horses, and pigs, characterized by the appearance of blisters in the mouth, which rapidly ulcerate (see Clinical and pathological aspects: vesiculovirus infection). Other 'vesicular viruses,' which include members of other families, cause similar lesions: for example, *Picornaviridae* (foot-and-mouth disease and swine vesicular disease) and *Caliciviridae* (vesicular exanthema virus). These viruses, of great economic importance for farming, are readily distinguished by morphological or serological criteria.

GENUS *LYSSAVIRUS*

Until 1956 and the first isolations of rabies-related viruses in Africa (King et al. 1994) and Europe (Schneider and Cox 1994), rabies virus (RABV) was believed to be antigenically unique. This warranted the creation of the genus *Lyssavirus* (Greek *lyssa*: rabies) for viruses responsible for rabies-like encephalitis. The genus was at first divided into four serotypes by antigenic crossreactivity with sera and mAbs, but European bat lyssavirus (EBLV) isolates remained unclassified (Dietzschold et al. 1988; Rupprecht et al. 1991; WHO 1992). Phylogenetic analysis of the nucleoprotein and glycoprotein genes further delineated six genotypes, the first four of which matched the serotypes (1) rabies, (2) Lagos bat, (3) Mokola, and (4) Duvenhage. The other two genotypes are EBL types 1 (5) and 2 (6) (Bourhy et al. 1993a).

Genotype 1 corresponds to classic RABV. It encompasses laboratory strains used for vaccine seed or control (challenge virus standard (CVS)) and many viruses isolated from various rabid domestic or wild animals worldwide. Members of genotypes 2–6 are rabies-related

viruses, which so far have been isolated only in the Old World. They have a narrower geographical distribution than rabies and, although they occasionally infect humans and domestic animals, they seem to infect preferentially certain specific host species. Lagos bat virus, Molokai virus, and Duvenhage virus were isolated in sub-Saharan Africa, principally from frugivorous bats, small mammals (shrews and rodents), and insectivorous bats, respectively (King et al. 1994). EBLV-1 and EBLV-2 are spreading widely in Europe, from the former USSR to Spain, and mainly infect insectivorous bats of the *Eptesicus* and *Myotis* species, respectively (Bourhy et al. 1992, 1993a; Schneider and Cox 1994; Amengual et al. 1997; Serra-Cobo et al. 2002).

In May 1996, a new lyssavirus was isolated from fruit-eating bats (flying foxes, *Pteropus alecto*) on the eastern coast of Australia, a country considered to be rabies-free since 1867. The same virus was also isolated from two other species of *Pteropus*, and from an insectivorous bat. Within the two following years, two fatal cases of human encephalitis caused by this new Australian bat lyssavirus (ABLV) were confirmed. Genetic and antigenic analysis of the virus, as well as cross-seroneutralization suggested that ABLV is closer to genotype 1, but sufficiently distinct to justify a new genotype (7) (Guyatt et al. 2003). The current seven genotypes are distributed in two phylogroups with distinct pathological and immunological properties: phylogroup I includes genotypes 1 and 4 to 7; phylogroup II comprises genotypes 2 and 3 (Badrane et al. 2001; Nadin-Davis et al. 2002). This classification is however bound to evolve, particularly as surveillance for bat lyssaviruses is re-enforced (Arguin et al. 2002; Reynes et al. 2004). Already, four additional divergent lyssaviruses have been isolated in bats of Central Asia, East Siberia, and the Black Sea region and are proposed as new genotypes: Aravan virus (ARAV), Khujand virus (KHUV), Irkut virus (IRKV), and West-Caucasian bat virus (WCBV) (Botvinkin et al. 2003; Kuzmin et al. 2003).

From the epizootiological point of view, rabies is maintained and transmitted by mammalian species serving as reservoirs and vectors (Baer 1991) (see section on Epizootiology and epidemiology below). They are distinguished from other mammals, which, although susceptible to infection, constitute epidemiological cul-de-sacs. Rabies exists in two major epidemiological forms: (1) canine rabies, of which stray dogs are the vectors, is responsible for >95 percent of the human cases in developing countries (Plotkin 1993; Meslin et al. 1994); and (2) sylvatic rabies, which involves wildlife worldwide. The wild vectors vary geographically and include terrestrial mammals, mainly carnivores, and bats. The last are vectors for six out of seven *Lyssavirus* genotypes characterized so far, and the exclusive vector in five of them. Phylogenetic analysis supports the evolution of lyssaviruses in bat vectors with occasional but regular spill over and host switching to carnivore vectors to extend the virus host range (Badrane and Tordo 2001). Polymerase chain reaction (PCR) technology has revolutionized the analysis of lyssavirus field isolates (Benmansour et al. 1992; Sacramento et al. 1992; Smith et al. 1992; Tordo et al. 1992a, 1993a, 1995; Bourhy et al. 1993a, b; Nadin-Davis et al. 1993, 1994; Kissi et al. 1995; Nel et al. 1993; Smith et al. 1993 and many others). In particular, phylogenetic analysis revealed that each genotype comprises variants with distinct genetic patterns typical of the geographical area and/or the species of isolation. In addition, in genotype 1 (classical rabies), a cosmopolitan lineage illustrates human influence in the worldwide spread of variant, probably transmitted by dogs present in Europe in earlier centuries (Kissi et al. 1995; Smith et al. 1992; Badrane and Tordo 2001). This variant has undergone successful adaptation to other wildlife species. Most of the current rabies vaccine strains derive from a wild strain of genotype 1 isolated by Pasteur (Tordo 1996).

GENUS *EPHEMEROVIRUS*

The genus *Ephemerovirus* was created to accommodate viruses in tropical and subtropical areas transmitted by hematophagous insects to cattle and water buffalo (Walker et al. 1992, 1994; Fu et al. 1994a). The name came from the prototype bovine ephemeral fever virus (BEFV), which was initially reported to cause a brief, transient fever. However, ephemeroviruses have also been isolated from healthy insects and cattle, as well as from cattle with acute febrile illnesses of major economic importance. BEFV has been found in Australia, Japan, China, the Middle East, and South Africa. Adelaide river virus (ARV), Kimberley virus, and *Berrimah virus* have been isolated in Australia, *Makalal virus* in Kenya, and *Puchong virus* in Malaysia (Calisher et al. 1989; Tordo et al. 2004).

Ephemeroviruses are genetically closer to vesiculoviruses (Wang et al. 1995) but are antigenically related to: (1) the unclassified rhabdoviruses Obodhiang virus, Kotonkan virus, and Kolongo virus that were isolated from, respectively, mosquitoes in the Sudan, midges in Nigeria, and birds in the Central African Republic; and (2) the rabies-related Lagos bat virus (Calisher et al. 1989). Obodhiang virus and Kotonkan virus are in turn serologically linked to the rabies-related Molokai virus (Calisher et al. 1989), which is the only lyssavirus replicating in *Aedes albopictus* cell cultures (Buckley 1975). Taken together, these data suggest that Obodhiang virus and Kotonkan virus may occupy an intermediate position between the genus *Lyssavirus*, adapted to mammals, and the genus *Ephemerovirus*, which has maintained a mixed arthropod–mammal cycle.

PLANT RHABDOVIRUSES

Although more than 100 plant viruses are listed as possible rhabdoviruses, their poor immunogenicity has

hampered serological grouping and classification was established at the genetic level (Jackson et al. 1999; Tordo et al. 2004). They are named according to the lesions they cause (e.g. necrosis, yellowing, and mosaic). Most are still classified according to the type of arthropod vector (aphid, leafhopper, etc.) (Jackson et al. 1987). Their transmission is mechanical, via arthropod or worm vectors, and most of those examined replicate efficiently in these vectors (Jackson et al. 1987). Two genera have so far been distinguished on replicative criteria. Members of the genus *Cytorhabdovirus* (prototype: lettuce necrotic yellows virus (LNYV)) replicate in the cytoplasm in association with viroplasms, and their morphogenesis takes place in vesicles of the endoplasmic reticulum. Members of the genus *Nucleorhabdovirus* (prototype: potato yellow dwarf virus (PYDV) replicate in the nucleus, morphogenesis takes place at the inner nuclear envelope and virions accumulate in the perinuclear spaces (Murphy et al. 1995; Jackson et al. 1999).

FISH RHABDOVIRUSES

The rhabdoviruses of fish cause hematopoietic necrosis, hemorrhagic septicemia, dropsy, swim bladder inflammation and hydrocephalus, diseases of major economic importance to the fish farming industry. Several are similar to vesiculoviruses based on structural similarities in protein composition and size. Phylogenetic analyses suggest placing these viruses in a separate genus, *Novirhabdovirus* (Benmansour et al. 1994; Morzunov et al. 1995; Schütze et al. 1995; Tordo et al. 2004). Fish rhabdoviruses grow in cell cultures at the ambient temperature of fish. They may be transmitted by an aquatic arthropod.

SIGMA VIRUS

Sigma virus is unique among the rhabdoviruses. It is a hereditary factor endemic in 20 percent of natural populations of the fruit fly *Drosophila*, in which it is propagated via the gametes. Sigma virus is not cytopathic and only slightly pathogenic in the infected flies, except that it confers sensitivity to CO_2. Replication is partly under the control of an antiviral host gene, *ref(2)P*, which is also required for male fertility (Dezélée et al. 1989). It has been suggested that sigma was a rhabdovirus trapped by a nonbiting fly and behaved as a hereditary factor to ensure its own survival (Brun 1984).

BIRD RHABDOVIRUSES

There have been rare isolations of rhabdoviruses from birds in America, Central Africa, and India. Very little is known from them, except that they replicate quite efficiently in insect cells (Zeller and Mitchell 1989; Travassos da Rosa et al. 2002).

Morphology and chemical composition

MORPHOLOGY

Under the electron microscope (Figure 2), animal rhabdoviruses are usually bullet-shaped with one round end and the other flat; plant rhabdoviruses are more frequently bacilliform (Figures 2 and 3); a few examples of conical forms have been observed in Obhodiang virus, Kotonkan virus, and bovine ephemeral fever virus and sometimes in RABV. The virion diameter is almost constant (50–100 nm), but lengths vary (100–430 nm), depending on the species or on the presence of defective interfering (DI) particles, which appear when the multiplicity of infection is high. The DI particles possess a truncated genome, are therefore defective in various viral functions, and must depend on infectious virions to complement their deficiency (Lazzarini et al. 1981). Their smaller genomes compete efficiently with normal genomes for replication and packaging into virions. Although their role during natural infection remains unclear, these subgenomic deletion mutants have been mimicked extensively to generate non-infectious recombinant viruses for reverse genetic studies (reviewed by Conzelmann 1996).

The virion is composed of two structural units (Figure 4). One is a central cylinder 50 nm in diameter with characteristic cross-striations composed of a tightly coiled RNP with helical symmetry. This is contained within the second unit, a lipoprotein membrane that is provided by the cell membrane during budding, and through which protrudes an array of knobbed glycoprotein spikes of about 10 nm in length.

CHEMICAL COMPOSITION

The chemical composition is approximately 74 percent proteins, 20 percent lipids (composition dependent on the host cell), 3 percent carbohydrates, and 3 percent RNA. The RNA is a single molecule of negative polarity (i.e. non-infectious). There are five major viral proteins with post-translational modifications that have been assigned either to the envelope or to the RNP structures by biochemical dissection of the virion with proteases and detergents (Delagneau et al. 1981; Tordo and Poch 1988b). From outside to inside:

- The membrane-anchored glycoprotein forms a trimer (Doms et al. 1987; Gaudin et al. 1992) that is glycosylated, and acylated with palmitic acid (Schmidt and Schlesinger 1979; Gaudin et al. 1991b). It constitutes the protruding spikes that are detected at the virion surface in electron microscopy (Delagneau et al. 1981; Gaudin et al. 1992).
- The central RNP is formed by an intimate association between the nucleoprotein (phosphorylated in RABV) and the RNA genome, which is thereby rendered insensitive to nucleases. The heavily phosphorylated

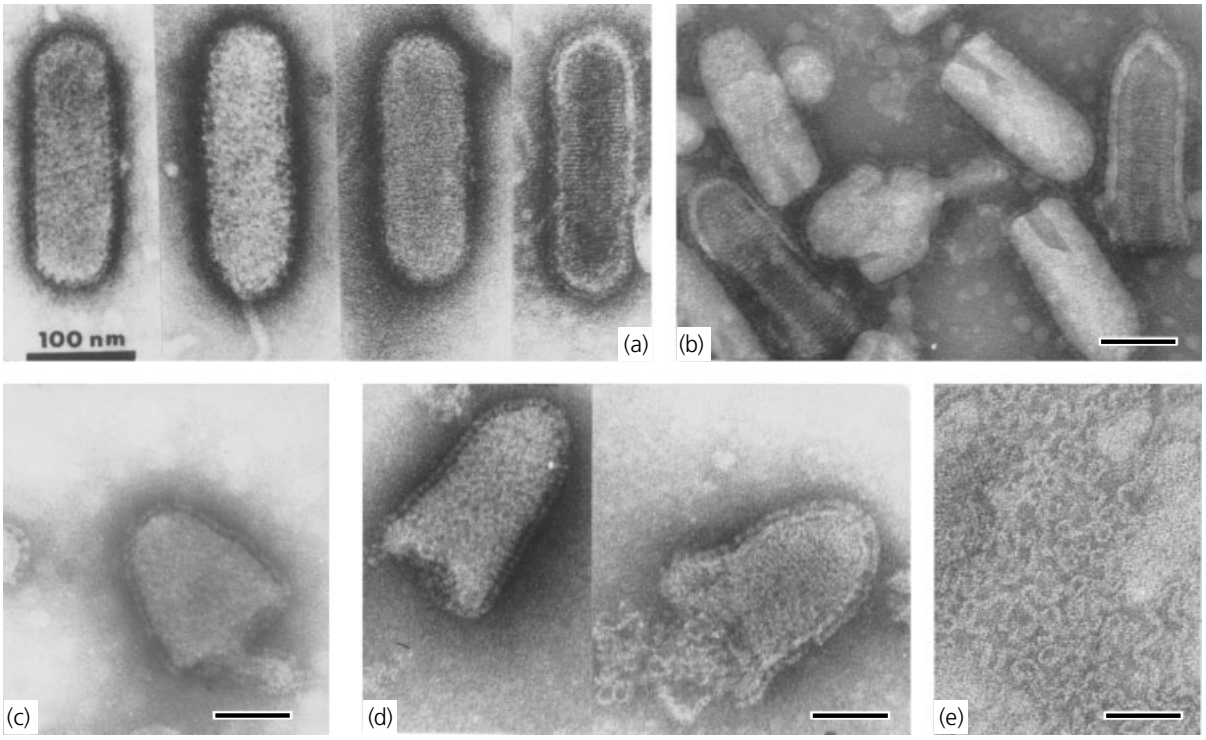

Figure 2 *Electron micrographs of rhabdoviruses.* **(a)** *Plant rhabdoviruses (courtesy of A.O. All scale bars, 100 nm.*

phosphoprotein and the large protein (polymerase) are also bound to the RNP, although less intimately.

- The exact position of the matrix protein remains controversial. It is unclear if it is embedded in the inner layer of the membrane, in the central axial channel of the RNP, or both (Barge et al. 1993; Gaudin et al. 1995a). RABV matrix protein is palmitoylated (Gaudin et al. 1991a), whereas VSV matrix protein is phosphorylated (Kaptur et al. 1995). A subpopulation of M protein is ubiquitinylated in order to recruit the cellular machinery necessary for budding (Harty et al. 2001).

For historical reasons, the nomenclature of the five basic proteins differs between viruses; reports of their relative number per virion also vary owing to the different assay techniques used (reviewed by Coll 1995). Despite these discrepancies, the proteins have similar functions and similar molecular weights. We shall use the conventional abbreviations N for nucleoprotein (50–55 kDa), P for phosphoprotein (35–40 kDa), M for matrix protein (25 kDa), G for glycoprotein (60–70 kDa), and L for the large polymerase (approximately 200 kDa).

Besides these main viral proteins, several rhabdoviruses have developed additional polypeptides for specific functions (see section on Implications for the structure of the genome below, and Figure 7). These additional proteins are rarely found in the viral particle, suggesting their involvement in replicative functions or interaction with the host cell. Conversely, several cellular proteins are reported as being packaged in the RABV and VSV virions, for example cellular kinases playing a major role in activation of the phosphoprotein for replicative functions (Gao and Lenard 1995b; Gupta et al. 1995) and heat shock proteins (Sagara and Kawai 1992). Cytoskeleton-associated proteins such as actin-binding proteins (from the ezrin–radizin–moesin family) are closely associated with the membrane glycoprotein and thereby promote incorporation of actin into the virion (Sagara et al. 1995). Their involvement in virion formation during the budding process is likely but the exact role of the cytoskeleton in the replication/assembly process remains unclear.

Infection cycle in the cell

Except for the sigma virus of *Drosophila*, which is passed vertically, the vast majority of rhabdoviruses are transmitted mechanically by injury, contacts, bite, or aerosols. Tissue tropisms and pathogenicity vary with individual viruses. The main steps of cell infection, shared by all the rhabdoviruses, will now be described (Figure 5). It should be noted that the data come mainly from studies on VSV and to some extent on RABV; current researches on other rhabdoviruses may reveal variations.

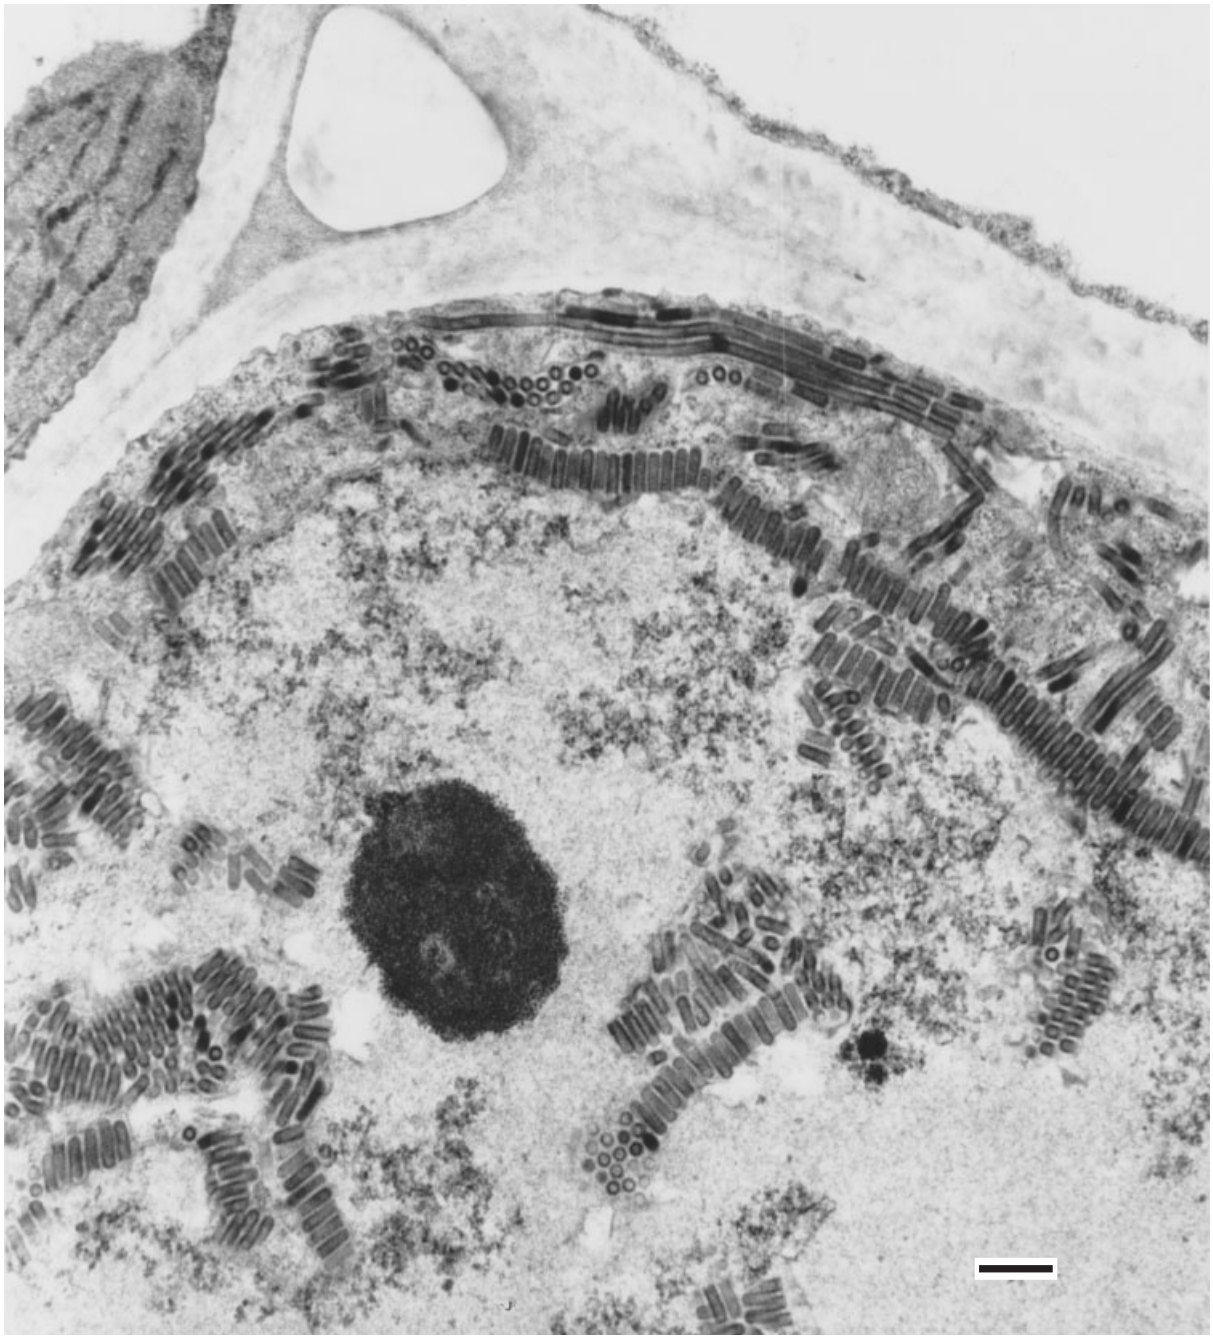

Figure 3 *Eggplant mottle dwarf virus within a cell nucleus. Note the long bacillary forms near the nuclear membrane. Bar, 4.5 μm (courtesy of R. Hull).*

PENETRATION INTO THE CELL

The attachment of the virus to the susceptible cell membrane is mediated by the glycoprotein, which recognizes specific receptors (Coll 1995). The nature of these receptors remains a matter of debate and the accumulated data reveal the complexity of the problem. In addition, most of the studies have been performed on strains that have been adapted for multiplication in established cell lines. For example, RABV isolates multiply and propagate exclusively inside neurons. Although adaptation does not abolish neurotropism, it renders the virus able to grow in nonneuronal cells. This adaptation may be due to the capability of fixed RABV strains to use ubiquitous receptors present on every cell type investigated to date. Ubiquitous receptors could be molecules such as phospholipids (Superti et al. 1984), gangliosides (Conti et al. 1988; Superti et al. 1986) or proteins (Wunner et al. 1984; Broughan and Wunner 1995; Gastka et al. 1996).

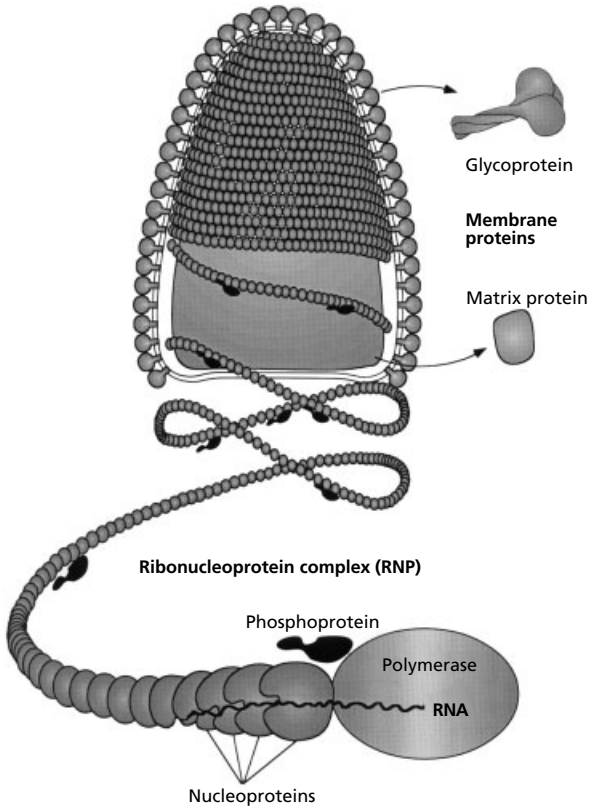

Figure 4 *Structure of the virion.*

Several studies indicated that the nicotinic acetylcholine receptor (nAChR) is a receptor for RABV (for a review, see Baer and Lentz 1991). Nevertheless, as the nAChR is located mainly on muscle cells and as RABV infects neurons that do not express nAChR (McGehee and Lorca 1995), it has been proposed that, in animals, this receptor enbles street RABV to multiply locally in myotubes only at the site of inoculation (Burrage et al. 1985). This would facilitate subsequent penetration into neurons. More recently, the neuronal cell adhesion molecule (NCAM) has been shown to facilitate viral entry in established laboratory cell lines (Thoulouze et al. 1998) and, thus, has been proposed to be another receptor for RABV. Finally, an expression cloning approach using soluble RABV glycoprotein led to the identification of the murine p75 neurotropin receptor as another putative RABV receptor (Tuffereau et al. 1998). Subsequent examination of other lyssaviruses' genotypes revealed that the glycoprotein from European bat lyssavirus 2 (but not that of the other genotypes) could also bind p75 (Tuffereau et al. 2001).

Phosphatidylserine has been proposed to be a receptor for VSV (Schlegel et al. 1983). Nevertheless, the absence of this lipid in the outer leaflet of cells (except when they are apoptotic) suggests that this putative receptor has to be considered with caution.

Very few things are known concerning the receptor of other members of the family. Recently, it has been suggested that fibronectin is a receptor for viral hemorrhagic septicemia virus (VHSV), a salmonid rhabdovirus (Bearzotti et al. 1999). This putative receptor was identified using mAbs generated against rainbow trout gonad cells. These mAbs have been selected for their ability to protect cells from VHSV infection. The blocking activity of these mAbs was also effective against other nonantigenically related fish rhabdoviruses. Interestingly, Broughan and Wunner (1995) had also suggested an involvement of fibronectin for RABV entry in BHK21 cells. Thus, fibronectin might play a general role in rhabdovirus entry.

Once bound, the virus is internalized into a cellular endosome. Then, as the pH decreases within the endosome, the viral membrane fuses with the vesicle one and the RNP is freed into the cytoplasm. Fusion of rabies virus with liposomes has been studied in detail (Perrin et al. 1982; Gaudin et al. 1991b, 1993). Fusion is only triggered at low pH and does not require any specific composition of the target membrane. It is optimal around pH 6, and is not detected above pH 6.4. These pH values are very similar to those determined for VSV (White et al. 1981; Carneiro et al. 2003) and for a fish rhabdovirus (Gaudin et al. 1999). Preincubation of rhabdoviruses at low pH in the absence of a target membrane leads to inhibition of viral fusion properties. However, loss of fusion properties can be reversed by readjusting the pH to above 7. This is the main difference between rhabdoviruses and other viruses fusing at low pH for which low pH-induced fusion inactivation is irreversible (reviewed in Gaudin 2000a).

Low pH-induced conformational changes of RABV glycoprotein and their relationships with fusion activity have been studied. At the virion surface, G can assume at least three different states that have been characterized by electron microscopy, sensitivity to proteases, and monoclonal antibody assays (Gaudin et al. 1991b, 1993, 1995b; Roche and Gaudin 2002). The native (N) state is detected at the viral surface at pH above 7. The activated (A) hydrophobic state is detected immediately after acidification. It interacts with the target membrane as a first step of the fusion process (Durrer et al. 1995). After prolonged incubation at low pH, G is in a fusion inactive conformation (I) that is antigenically distinct from the N state. There is a pH-dependent equilibrium between these states which is shifted toward the I state at low pH (Roche and Gaudin 2002). Similar results have been obtained for VSV G (Clague et al. 1990; Doms et al. 1987; Pak et al. 1997; Carneiro et al. 2003). Finally, the results obtained so far suggest that, for rhabdoviruses, the sequence of events leading to membrane fusion are very similar to that of other enveloped viruses (Gaudin 2000b) and that the fusion complex is made of several trimers (Roche and Gaudin 2002).

Once delivered into the cytoplasm the RNP is ready to serve as a template for gene expression. In the

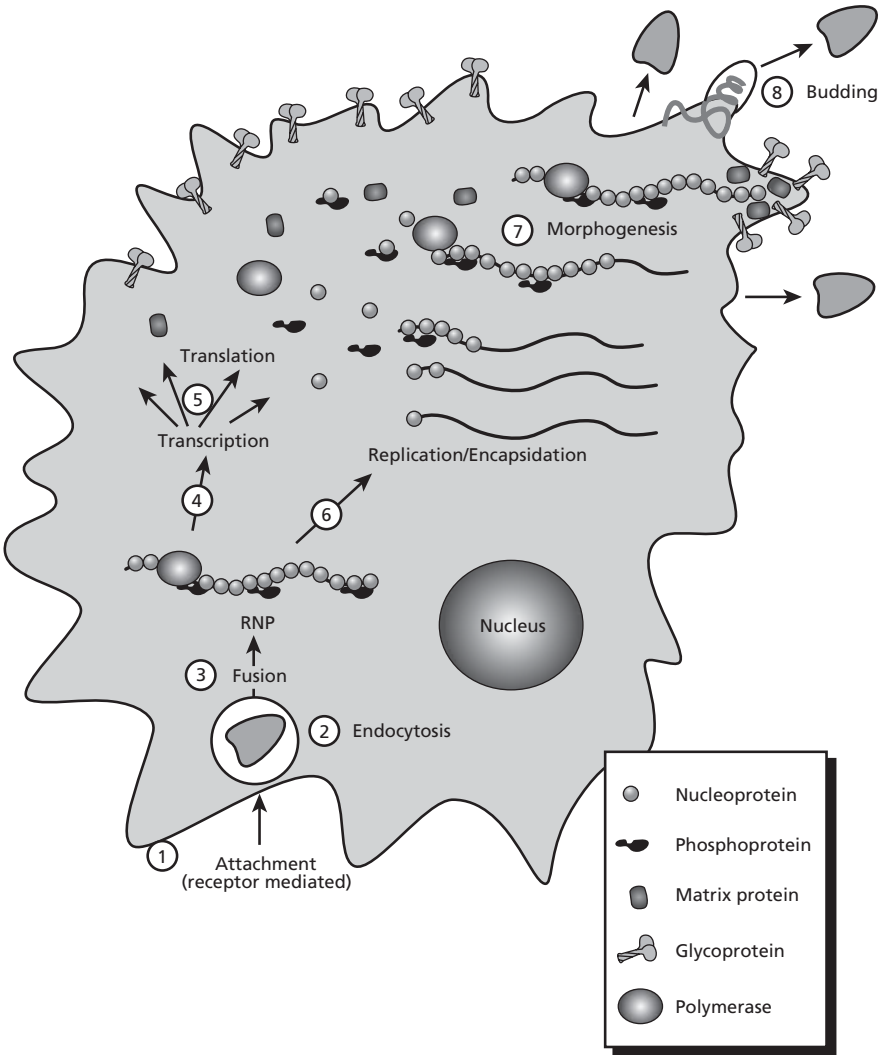

Figure 5 *Example of the rhabdoviral cell infection cycle (rabies virus).*

particular case of neuron infection by RABV, the RNP is first transported by retrograde axonal flow and replicates only in the perikaryon. Recently, it has been demonstrated that the phosphoprotein of lyssaviruses binds the LC8 light chain of the dynein motor suggesting that dynein might play a role in the transport of the RNP (Raux et al. 2000; Jacob et al. 2000). Nevertheless, as an RABV mutant, having a mutated phosphoprotein unable to bind LC8, behaves as wild-type virus even in animals, the exact role of this interaction is not clear (Mebatsion 2001).

Gene expression takes place exclusively in the cytoplasm and only a limited number of viral transcripts or proteins reach the nucleus where their exact role is not clear. In the case of vesiculoviruses, M protein, by interacting with nuclear pores, enhances the availability of the cellular translation machinery by inhibiting the export of cellular mRNAs from the nucleus (Her et al. 1997; Petersen et al. 2000; von Kobbe et al. 2000). In the case of RABV, the *P* gene products are able to interact with the nuclear PML bodies. As these nuclear structures are involved in the resistance of many cells to viral infection, this interaction is supposed to modulate the cellular innate immune response (Blondel et al. 2002).

Mechanism of genome expression

Mechanisms of rhabdovirus genome expression have been more extensively explored on the VSV model (reviews: Banerjee 1987; Tordo and Poch 1988b; Vidal and Kolakofsky 1989; Banerjee and Barik 1992; Tordo and Kouznetzoff 1993; Barr et al. 2002; Kolakofsky et al. 2004; Whelan et al. 2004). Because the rhabdovirus genome has negative polarity, it must be transcribed to produce the complementary positive-strand mRNAs. The RNP serves as template for two successive RNA synthetic functions (Figure 6): transcription then

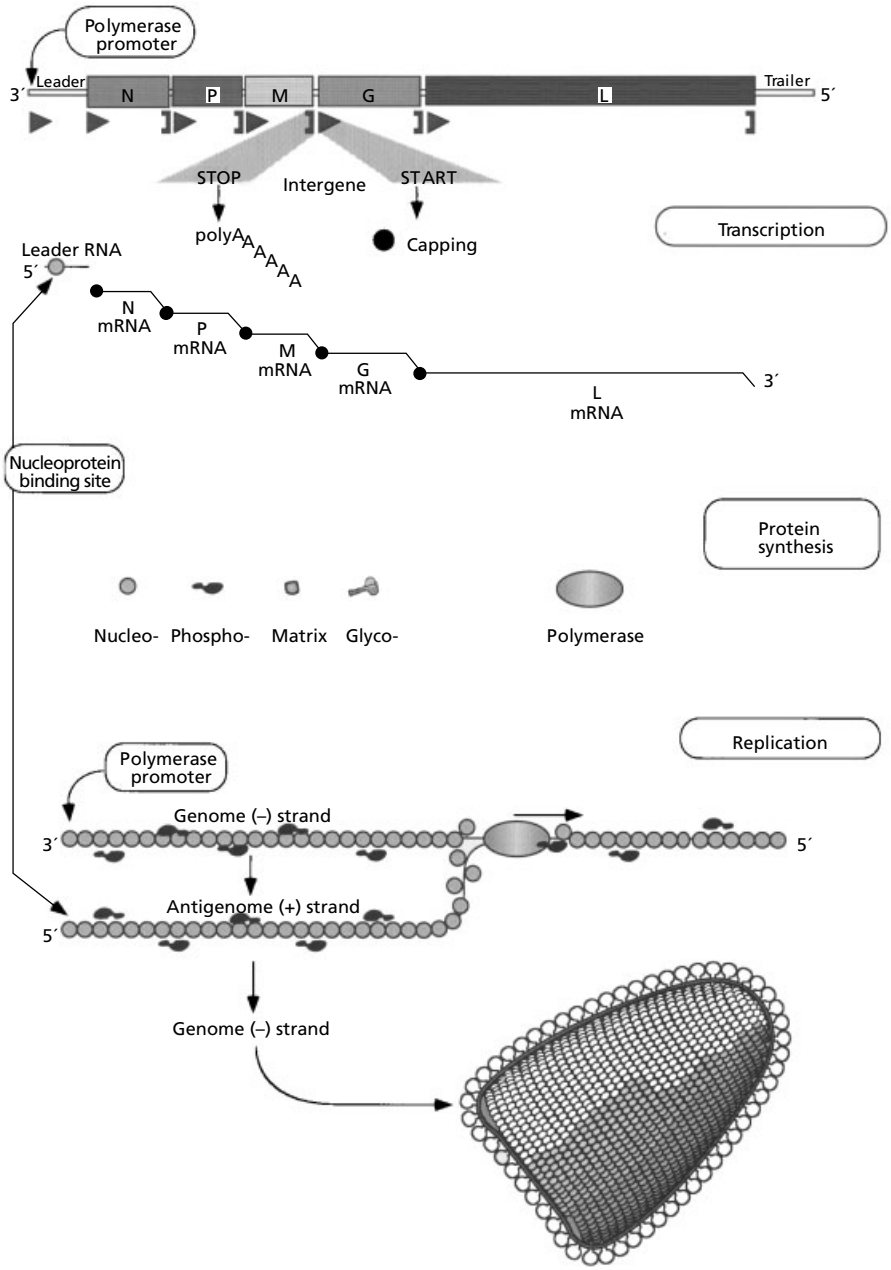

Figure 6 *Transcription, translation, and replication mechanisms of rhabdoviruses.*

replication. For both, the viral polymerase recognizes a promoter at the 3′ end of the encapsidated genome, and proceeds towards the 5′ end. There is still a debate whether there is a single 3′or two different promoters for transcription and replication. The difference between transcription and replication is determined by the processivity of the polymerase, that influences the way it progresses either sequentially or continuously. Transcription gives rise to mostly monocistronic transcripts: first a short noncapped, nonpolyadenylated leader RNA, then five (or more) mRNAs coding for the viral proteins (Figure 6). This sequential progression depends on the recognition of short conserved *cis*-acting signals, bordering the cistrons, which initiate start (and capping) and stop (and polyadenylation) of the mRNAs. When the transcriptase stops transcribing at one polyadenylation signal, it scans in both directions for the nearby (re)start mRNA signal. This strategy results in sequential transcription from the 3′ to the 5′ cistrons, associated with a progressive attenuation due to the cumulative probability of the polymerase to fall off the template during scanning. Thus, the length of the scanned intergenic region influences the efficiency of re-initiation. Bidirectional scanning permits overlapping cistrons when the polymerase backtracks and restarts within the cistron upstream.

In contrast, the replicase acts continuously and generates a full-length positive-strand antigenome that is in turn replicated into negative-strand genomes for the progeny virions. To become functional templates, the genomes and antigenomes must be encapsidated into RNP, which protects them from the action of nuclease. This is why viral protein synthesis is a prerequisite for replication. There is an entry site for the nucleoprotein at its 5′ end to promote the concomitant encapsidation of the growing RNA. During the transcription step, leader RNA carrying this entry site is released. During replication, the 5′ end remains linked to the growing RNA genome, which is progressively encapsidated.

The main event influencing continuous synthesis by the polymerase and its switch from transcription to replication mode is the concomitant (anti)genome encapsidation. Here, the amount of nucleoprotein available is decisive (Vidal and Kolakofsky 1989; Horikami et al. 1992). At low levels, the polymerase stops at the end of the leader RNA and immediately re-initiates at the start signal of the first mRNA. This initiation prevents encapsidation of the mRNAs and causes a shift to the sequential transcription mode, in which elongation is independent of encapsidation. This results in an increase in viral protein. At high levels of nucleoprotein, the concomitant encapsidation prevents the polymerase stopping at the end of the leader RNA, causing a switch into the processive mode and the replicase becomes unable to recognize the following start and stop signals.

The translation step separating transcription from replication is ensured by cellular mechanisms. The classic scanning model (Kozak 1989), predicting that ribosomes bind to the capped 5′ end of the mRNA and scan downstream, is generally accepted. Thus, most of the viral proteins start at the first AUG codon along the mRNA. Exceptions to this rule have, however, been noted during translation of the P mRNA. In addition to the normal P protein, VSV encodes two other polypeptides starting at distal AUGs, one in the same open reading frame (ORF) (Herman 1986) and one in another ORF (Spiropoulou and Nichol 1993). By contrast, RABV uses at least four AUGs in the same ORF. Translation of these proteins is initiated by a leaky scanning mechanism (Chenik et al. 1995). The resulting polypeptides are either cytoplasmic or nuclear, depending on the accessibility of corresponding export and import signals, and thereby interact with various cellular partners (Blondel et al. 2002). All the viral proteins are expressed in the cytosol by free polyribosomes, except the glycoprotein which is synthesized as a transmembrane protein by polyribosomes associated with membranes of the rough endoplasmic reticulum (RER). It is then transported to the cytoplasmic membrane via the Golgi apparatus. Because of the acidity of the RER and Golgi compartments, the glycoprotein is synthesized in a conformation inactive for fusion, thus impairing its interaction with viral cellular membranes during transport. Once at the cell surface, the pH increases and the conformation reverts to the native type (Gaudin et al. 1995b, c).

Several viruses have developed variations on this general model of expression. The ephemeroviruses use a polycistronic strategy to express both structural and regulatory genes (Wang and Walker 1993; Wang et al. 1994). In the case of vaccine strains of RABV (PV, ERA, SAD), there are alternative terminations for the matrix and glycoprotein cistrons (Tordo and Poch 1988a, Morimoto et al. 1989; Sacramento et al. 1992, Tordo et al. 1992b; Tordo and Kouznetzoff 1993). Two consecutive stop (polyadenylation) signals are alternatively recognized by the transcriptase to produce either a small or a large mRNA. It has been proposed that alternative termination, by modifying the length of the scanned intergenic region, could influence the transcription level of the distal cistron, resulting in a regulation tool for genome expression (Tordo and Poch 1988a; Tordo et al. 1992b; Tordo and Kouznetzoff 1993). This regulation could be partly under the control of specific cellular factors, reinforcing the importance of the intracellular environment for cell susceptibility noted above, and suggesting that it might be worthwhile to study rabies neurotropism at the transcriptional level.

Implications for the structure of the genome

The genome of rhabdoviruses varies in length between 11 kb (*Vesiculovirus*) and 15 kb (*Ephemerovirus*) (see Figure 7). Its structure subserves a typical expression mechanism. For both the minus-strand genome and the plus-strand antigenome the promoter for the polymerase is located at the 3′ end (Smallwood and Moyer 1993); the entry site of the nucleoprotein for encapsidation is at the 5′ end (Moyer et al. 1991) (Figure 6). As the minus-strand genome is template for either transcription or replication, while the plus-strand antigenome is only template for replication, the promoter for replication of the plus-strand antigenome is logically much stronger than that of the minus-strand genome (Barr et al. 2002; Le Mercier et al. 2003; Whelan et al. 2004). The consequence of the preservation of these important signals is that the extremities of both positive and negative strands are complementary, although a hairpin structure was never evidenced in vivo. Indeed, a minigenome consisting of only 50 residues from each end is sufficient to ensure transcription, replication, encapsidation, and envelopment (Pattnaik et al. 1995). In addition, when the complementarity between extremities is increased by mutagenesis, replication rather than transcription is favored (Wertz et al. 1994; Whelan et al. 2004). It is interesting that most of the DI particles effectively mimic such minigenomes; those with extensive complementary ends are the most efficient for interference.

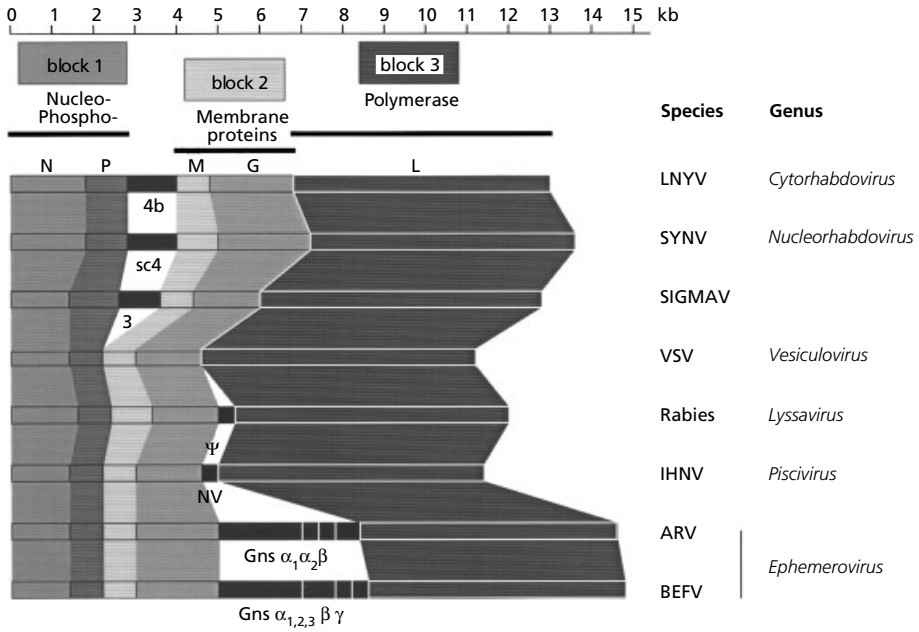

Figure 7 *Structural comparison of the rhabdovirus genomes. ARV, Adelaide River virus; BEFV, bovine ephemeral fever virus; IHNV, infectious hematopoietic necrosis virus; LNYV, lettuce necrotic yellows virus; SYNV, sonchus yellow net virus; VSV, vesicular stomatitis virus.*

Besides the conserved extremities, the genome possesses a modular structure with the juxtaposition of cistrons independently controlled by signal sequences. Indeed, the progressive decrease in the rate of transcription from the 3′ to the 5′ end implies that the position of a cistron directly influences its rate of expression. This explains why rhabdoviruses have conserved very similar genome organizations into three blocks (Figure 7) (Tordo et al. 1992a). Block 1 at the 3′ end encodes proteins required in large quantities (N, P), particularly the nucleoprotein that balances the switch between transcription and replication. Block 2 encodes the membrane proteins (M, G). Block 3 at the 5′ end encodes the viral polymerase (L), required in limited amounts. This modular structure accepts some flexibility, and in several viruses typical genes are inserted that are adapted to their particular biology. Between blocks 1 and 2, the plant rhabdoviruses encode a protease-like protein (sc4, 4b) that corresponds to the movement protein needed for passage of the virus through plasmodesmata, thus allowing cell-to-cell transmission despite the presence of the cell wall (Scholthof et al. 1994). At the same position the sigma virus encodes a protein related to the reverse transcriptase of retro-elements (ORF 3) (Landès-Devauchelle et al. 1995). Between blocks 2 and 3, the ephemeroviruses encode a second heavily glycosylated glycoprotein (Gns) which probably arose from a sequence duplication of the *G* gene (Wang and Walker 1993). Gns is nonstructural and of unknown function, as are the additional small proteins (α, β, γ) encoded consecutively (Wang et al. 1994) and the NV protein of the fish rhabdovirus IHNV (Morzunov et al. 1995; Kurath et al. 1997). It is interesting that, at the same position between blocks 2 and 3, lyssaviruses conserve a large noncoding area initially termed 'pseudogene' ψ because it could represent a vestige of the multiple changes occurring in this region during rhabdovirus evolution (Tordo et al. 1986, 1992b; Ravkov et al. 1995).

Exit from the cell

Before viral budding, transcription and replication are inhibited and, simultaneously, the RNP becomes intensively condensed and coiled. A considerable body of evidence suggests that this morphological role during virion assembly is played by the matrix protein (see Morphology and chemical composition above). In parallel, glycoproteins are concentrated in particular regions of the plasma membrane (Brown and Lyles 2003). After the cytoplasmic maturation step, the virion leaves the cell by budding, the lipid envelope being provided by the host cell membrane. Most rhabdoviruses bud from the plasma membrane and some from internal cell membranes. The plant rhabdoviruses bud either from the endoplasmic reticulum (cytorhabdoviruses) or from the inner nuclear envelope (nucleorhabdoviruses) and accumulate in perinuclear spaces (Jackson et al. 1987).

Functional role of the viral polypeptides

The advances in genetic manipulation of negative-strand RNA viruses have greatly facilitated the functional

dissection of viral genes and proteins by reverse genetics (see Conzelmann 1996 for a review, and also Lawson et al. 1995; Whelan et al. 1995; Kretzschmar et al. 1996; Schnell et al. 1996; Le Mercier et al. 2002). The use of these viruses has greatly improved the understanding of viral pathogenesis and has provided stable vectors to express foreign genes and develop new vaccines (Schnell et al. 1996; Dietzschold et al. 2003; McKenna et al. 2003; Faber et al. 2004). In addition, studies of the interactions between the proteins and the backbone RNA genome are being pursued by various physical (electron microscopy and crystallography), biochemical, and immunological methods.

THE RIBONUCLEOCAPSID COMPLEX (RNP)

The RNP is the minimum structure needed to mediate RNA synthesis. The N protein RNA is the template whereas the polymerase function is catalyzed by the L and P proteins (Conzelmann and Schnell 1994). Minus-strand as well as plus-strand genomic templates are so tightly complexed with the N protein that they are resistant to both RNases and post-translational gene silencing by short interfering RNA (Bitko and Barik 2001). The RNP complex possesses a typical helical form (Schoehn et al. 2001). Chemical probing experiments on VSV RNP showed that the N protein binds to the sugar–phosphate backbone, exposes the Watson–Crick positions of the bases to the solvent and modifies their reactivity (Iseni et al. 2000). Indeed, the nucleoprotein melts secondary RNA structure (helical activity) and favors transcription/replication without the need for dissociation. L is the RNA-dependent RNA polymerase that possesses most of the required enzymatic activities: RNA synthesis (De and Banerjee 1984); mRNA capping and methylation (Horikami and Moyer 1982); mRNA polyadenylation (Hunt et al. 1984; Hunt and Hutchinson 1993); and possibly kinase activity on the P protein (Barik and Banerjee 1992). P is a regulatory cofactor for which various functions have been proposed: mediating interaction between L and the N-RNA template (Isaac and Keene 1982; De and Banerjee 1984); transiently displacing the N protein to gain access to the RNA (Hudson et al. 1986); complexing the soluble N to maintain it in a replication-competent form for encapsidation (Masters and Banerjee 1988; Howard and Wertz 1989; La Ferla and Peluso 1989; Mavrakis et al. 2003).

The nucleoprotein N appears as a two-modular protein, with a large, compact (resistant to proteases) and well-conserved NH_2-terminal core binding the RNA, and a smaller, flexible and variable COOH tail which is exposed and ensures contact with the P protein (Banerjee et al. 1989; Iseni et al., 1998; Schoehn et al. 2001). RNA-binding sites with noncanonical motifs have been tentatively identified for RABV and viral hemorrhagic septicemia virus (Kouznetzoff et al. 1998; Said et al. 1998). Site-directed and deletion mutagenesis and two-hybrid method suggested domains important for N–N and N–P interactions (Chenik et al. 1994; Jacob et al. 2001; Schoehn et al. 2001). The rabies virus N protein N is phosphorylated (unlike VSV). The role for this phosphorylation due to a cellular kinase is unclear; phosphate hydrolysis could produce free energy for transcription and replication (Wu et al. 2002, 2003).

The interaction network of the P protein within the RNP has been extensively studied, (Chenik et al. 1994, 1998; Fu et al. 1994b; Gao and Lenard 1995a; Jacob et al. 2001; Takacs and Banerjee 1995). The rabies virus P protein seems to be composed of two independent domains that nicely outline its intermediate position between the L and N–RNA template. The NH_2 half encompasses the L binding site close to the N terminus (amino acids (aa) 1–52 particularly 1–19) as well as a weak N-binding site (aa 1–185 particularly 69–138) which probably interacts and maintains the soluble N in an encapsidation-competent form (Mavrakis et al, 2003). The COOH half comprises a strong N-binding site (aa 176–297), which likely binds the N–RNA template. The atomic structure of the COOH half (186–297) has been determined and the residues important for N–RNA binding mapped (Mavrakis et al. 2004). The COOH half is a monomer and the oligomerization of P rather involves the NH_2 half (particularly aa 52–189). The phosphorylation of P is essential for regulating its activity in transcription (Barik and Banerjee 1992; Beckes and Perrault 1992; Gao and Lenard 1995a) and replication (Chang et al. 1994). P subspecies varying in degree of phosphorylation and in physical state (soluble, multimeric, or complexed with N or L) have different activities in relation to both functions (Tuffereau et al. 1985; Gao and Lenard 1995a; Richardson and Peluso 1996). The P phosphorylation step is ensured at precise sites by different cellular kinases packaged in the virion: the casein kinase-II and an L-associated kinase (LAK) for VSV (Barik and Banerjee 1992; Beckes and Perrault 1992; Chen et al. 1997; Gao and Lenard 1995a, 1995b; Gupta et al. 1995); the protein kinase C (isomers α, β, and γ and another cellular rabies specific phosphokinase (RVPK) for rabies virus. It is interesting that protein kinase Cγ is mostly found in nerve tissue, and could provide another tissue-specific element in the regulation of rabies transcription. Phosphorylation is thought to promote conformational changes. Phosphorylation is required for oligomerization of the VSV but not of the rabies P protein (Gao and Lenard 1995b, Gigant et al. 2000). The small C and C′ basic proteins encoded in a second ORF on the *P* gene (Spiropoulou and Nichol 1993; Kretzschmar et al. 1996) are unnecessary for VSV growth in tissue culture (Kretzschmar et al. 1996). It has been suggested that they play a role in viral pathogenesis or transmission by insect vectors (Kretzschmar et al. 1996).

Due to very limited amounts in the virion as well as in infected cell, less is known on the structure–function of

the L polymerase. The region binding the P protein is located at the COOH side: in aa 1638–1873 for VSV (Canter and Perrault 1996); in the C-terminal 566 aa for rabies virus (Chenik et al. 1998). The sequence alignment of L proteins from *Mononegavirales* has provided a structure that is consistent with its multifunctional nature: six conserved domains (probably carrying the catalytic activities) are concatenated by variable hinge regions (Poch et al. 1990). The domains seem to be autonomous as suggested by complementation between L mutants (Flamand 1980). Putative functions have been tentatively assigned to several domains (Poch et al. 1990). In particular, domain III possesses four or five hyperconserved motifs similar in structure and position to those found in all RNA-dependent polymerases (Poch et al. 1989; Müller et al. 1994) and also in DNA-dependent polymerases, although more distantly (Delarue et al. 1990). Distant from this 'polymerase module,' domain VI (500 aa toward the COOH side) is typical from 2′-*O*-ribose-methyltransferases (Bujnicki and Rychlewski 2002; Ferron et al. 2002) and could be involved in the methylation during mRNA capping (Abraham et al. 1975; Gupta et al. 2002). This predictive analysis has guided the first trials of site-directed mutagenesis, which basically confirmed the functional importance of the predicted motifs (Sleat and Banerjee 1993; Schnell and Conzelmann 1995). A more systematic analysis by extensive sequence comparison between wildtype and mutant strains of VSV suggests that residues in the interdomain V–VI are essential for polyadenylation and thermosensitivity (Hunt and Hutchinson 1993). In addition, it was suggested that host factor(s) might be required for the activity of the L protein (Mathur et al. 1996).

MEMBRANE PROTEINS

M is a small protein (slightly more than 200 amino acid residues) comprising a positively charged amino terminal part (Poch et al. 1988). For VSV, this amino terminal part can be removed by proteolysis (Ogden et al. 1986). Cleavage of VSV M by thermolysin provided a resistant core (Mth) composed of two noncovalently associated fragments (residues 48–121 and 122–(or 123 or 124 depending on the thermolysin cleavage site) 229) (Gaudier et al. 2001) that could be crystallized allowing the determination of its structure (Gaudier et al. 2002).

The M protein is involved in the late steps of the infectious cycle. It condenses the RNP into a tightly coiled helical structure (Newcomb et al. 1982). This tightly coiled structure seems to be formed near cellular membranes where M is bound (Odenwald et al. 1986; Flood and Lyles 1999). Strong evidence that M plays a major role in VSV budding comes from studies of VSV temperature-sensitive mutants affected in budding that were shown to be mutated in the *M* gene and were complemented by wild-type plasmid-derived M (Flamand 1970; Lyles et al. 1996). More recently, an M-deficient RABV mutant has been obtained using reverse genetic (Mebatsion et al. 1999). In the absence of M, infectious particles were mainly cell associated and the yield of cellfree infectious virus was largely reduced demonstrating the role of RABV M in virus budding. Supernatants from cells infected with the M-deficient RABV did not contain the typical bullet-shaped rhabdovirus particles, but instead contained long, rod-shaped virions, showing severe impairment of the virus formation.

Two biochemical properties of VSV M have been studied, auto-association and membrane-binding VSV. M self-associates into large multimers at physiological NaCl concentration (McCreedy et al. 1990), a process initiated by trypsin-sensitive nucleation sites that is reversed by increasing the salt concentration (Gaudin et al. 1995a). M self-association could be important for nucleocapsid compaction and may constitute a driving force for budding. VSV M cell membrane association is also necessary for budding. This interaction was proved to be extremely stable in vivo as it is not destabilized by harsh treatments such as 2M KCl or pH 11 (Bergmann and Fusco 1988; Chong and Rose 1993, 1994). The regions of the protein involved in membrane association are not completely defined: hydrophobic photolabeling has identified the amino-terminal region of the protein (Lenard and Vanderoef 1990), but M mutants deleted from the amino-terminal domain still interact with cellular membranes, suggesting that another domain of the protein is involved (Chong and Rose 1994; Ye et al. 1994). Indeed, the structure of Mth revealed a hydrophobic patch at the surface of the protein. This patch is located close to a hydrophobic loop containing the cleavage site of thermolysin and surrounded by basic residues (two arginines and three lysines). The combined presence of hydrophobic and basic residues suggests that it is a likely candidate for being a region interacting with membranes (Gaudier et al. 2002).

The amino-terminal part of the matrix protein contains two short motifs (PPxY and PSAP) that are supposed to recruit the cellular partners involved in the ultimate step of the budding process (i.e. the fission step). The PPxY motif has been shown to be recognized by an E3 ubiquitin ligase (Harty et al. 2001) and to influence budding efficiency (Jayakar et al. 2000). The exact role of the PSAP motif remains to be determined.

The functions of M are not limited to viral assembly and budding. Both VSV and RABV M inhibits the transcription of the viral genome (Clinton et al. 1978; De et al. 1982; Finke et al. 2003). RABV M acts also as a replication stimulatory factor (Finke et al. 2003). For RABV M, a mutation has been identified that affect the function of M only in regulation of RNA synthesis, but not in assembly and budding, providing evidence that these functions are genetically separable (Finke and Conzelmann 2003).

Finally, VSV M expression causes the rounding of cells, a phenotype characteristic of VSV infection (Blondel et al. 1990; Melki et al. 1994) that is probably a consequence of M-induced apoptosis (Kopecky et al. 2001; Kopecky and Lyles 2003). As mentioned above, it also inhibits the export of RNAs from the nucleus (Her et al. 1997; Petersen et al. 2000; von Kobbe et al. 2000). This export inhibition may be the cause of M-induced inhibition of host-cell transcription (Black et al. 1993; Black and Lyles 1992). It has also been proposed that host transcription shut-off is induced by an effect of M on the transcription factor TFIID, which was found to be ineffective in the cells where M is expressed (Yuan et al. 1998). All these cytopathic effects of M protein explain why VSV is deleterious to all types of cell.

The glycoprotein (reviewed by Coll 1995) has the typical structure of group I transmembrane proteins. An NH_2 terminal signal peptide of about 20 amino acids (aa) in length serves the translocation of nascent protein through the RER membrane and is cleaved in the mature protein. A hydrophobic transmembrane segment (approximately 20 aa) remains embedded in the viral envelope. It separates the 'cytoplasmic' COOH domain (about 50 aa), interacting with internal viral proteins, from the glycosylated NH_2 ectodomain (approximately 450 aa). The glycosylation and palmitoylation sites have been mapped (Rose et al. 1984; Gaudin et al. 1991a; Shakin-Eshleman et al. 1992). The role of glycosylation in correct folding of G ectodomain has been studied in detail (Machamer and Rose 1988; Hammond and Helenius 1994; Mathieu et al. 1996; Gaudin 1997). A map of the disulfide bridges of the ectodomain of VHSV G has also been established (Einer-Jensen et al. 1998) that has allowed a general model for the rhabdoviral G (Walker and Kongsuwan 1999). It has to be noted that VSV G and some of its thermosensitive mutants have been used as model glycoproteins to elucidate how membrane proteins are transported all along the secretory pathway. Particularly, VSV G has been used to study the quality control mechanisms that operate in the endoplasmic reticulum (ER) and the downstream compartments to ensure that only proteins that are correctly folded are transported (e.g. Hammond and Helenius 1994; Cannon et al. 1996).

The important functions of the ectodomain have also been mapped. Based on sequence similarity with snake venom curare-mimetic neurotoxins (Lentz et al. 1984; Rustici et al. 1993; Tordo et al. 1993b) and further studies using anti-idiotypic antibodies (Hanham et al. 1993), the 190–203 aa sequence of rabies glycoprotein ectodomain has been implicated in the recognition of the nicotinic AChR. By selection of RABV mutants that were not neutralized by a soluble form of p75, the domain of interaction with this receptor has been shown to implicate aa 318 and 352 (Langevin and Tuffereau 2002). The region involved in fusion has also been searched by insertion and directed mutagenesis. Different sites modified the ectodomain structure in such a way that fusion activity was blocked or modified (Li et al. 1993; Zhang and Ghosh 1994; Fredericksen and Whitt 1995, 1996). However, the exact locations of the fusion peptide were mapped by photolabeling to the following sequences: aa 102–179 for RABV, 58–221 for VSV (Durrer et al. 1995). Taken together, these data suggest that a sequence corresponding to aa 118-136 of VSV enriched in prolines and aromatic residues might constitute G fusion peptide. However, the data obtained during these studies have also indicated that a second region of the protein, located in the carboxy-terminal part of the ectodomain (around aa 400), controls the low pH-induced conformational changes of G (Gaudin et al. 1996; Shokralla et al. 1998). Finally, several residues of the ectodomain seem to play a crucial role in pathogenicity and virulence (Tordo et al. 1993b). For RABV, neurovirulence is directly linked to the maintenance of a basic residue in position 333 (Tuffereau et al. 1989) that may be involved in p75 recognition (Tuffereau et al. 1998). Mutation at this residue reduced the categories of neurons sensitive to infection (Coulon et al. 1994).

Antigens

In the case of RABV, several hundred mAbs have been used to characterize the antigenic structure of G making this protein one of the best known viral antigens (Raux et al. 1995; Benmansour et al. 1991; Préhaud et al. 1988; Seif et al. 1985; Lafon et al. 1983; Wiktor and Koprowski 1980). RABV G has two major antigenic sites that are antigenic sites II and III. Antigenic site II is located between positions 34 and 42 and positions 198 and 200 (Préhaud et al. 1988). These peptides are joined by a disulfide bridge and maintained together in the tertiary structure of G (Dietzschold et al. 1982). Antigenic site III extends from amino acids 330 to 338 (Seif et al. 1985). Beside these major antigenic sites, one minor antigenic site and a few isolated epitopes have been described (Lafay et al. 1996; Raux et al. 1995; Benmansour et al. 1991; Dietzschold et al. 1990).

The immune response against lyssaviruses is complex; the response to RABV has been extensively studied. Although all the viral proteins are antigenic, their roles in protection vary (Lafon 1994; Xiang et al. 1995; Drings et al. 1999). Their respective importance has been defined by recombinant DNA techniques (Tordo 1991; Perrin et al. 2001). Two of them, G and N, are of primary importance, the phosphoprotein P being of less significance. Purified G protein protects against intracerebral challenge with RABV, and is the only antigen that consistently induces virus-neutralizing antibody (Wiktor et al. 1973). This property mainly depends on the preservation of its three-dimensional structure,

although a linear neutralizing epitope has been identified (Bunschoten et al. 1989; Benmansour et al. 1991; Ni et al. 1995). On the other hand, the glycoprotein shares with the N and P proteins of RNP the capacity to induce a cellular immune response, involving, respectively, T helper cells (Th) and cytotoxic T cells (Tc) (Lafon 1994; Xiang et al. 1995). Purified RNP protects against challenge by peripheral routes, probably through a cross-help mechanism between N-specific Th lymphocytes and G-specific B lymphocytes producing neutralizing antibodies (Dietzschold et al. 1987; Lodmell et al. 1991; Lodmell et al. 1993). An effective role of the Tc response in protection remains to be clearly demonstrated (Xiang et al. 1995). It is interesting that the G and N antigens conserve their immunogenic properties when administered orally (Hooper et al. 1994). This property is used extensively in large vaccination campaigns with vaccinia or adenoviruses expressing recombinant G protein (see Control).

Most of the current rabies vaccine strains derive from a wild strain isolated by Pasteur (Tordo 1991). This was initially passaged intracerebrally in rabbits until the incubation period shortened and became 'fixed' at 5–8 days. From this, multiple passages in animal brain and cell culture were performed. Vaccine strains belong to genotype 1 (causing classic rabies) and protect against homologous isolates (Lodmell et al. 1995), but do not protect efficiently against rabies-related viruses in genotypes 2–6 that also pose possible threats to humans (Bahloul et al. 1998; Badrane et al. 2001). Work is in progress to improve the protection offered by the vaccine by increasing the number of genotypes against which it is effective. The conserved N protein, a strong inducer of Th cells, may be important in this respect. It behaves as a superantigen in humans and BALB/c mice, activating Vβ8 and Vβ6 T cells, respectively (Lafon et al. 1992; Lafon 1994). The antigenic sites for B and T cell responses have been extensively mapped along the G, N, and P viral antigens by sequencing mutants resistant to neutralizing antibodies or by measuring the reactivity of chemically cleaved or synthetic peptides (Bunschoten et al. 1989; Benmansour et al. 1991; Ertl et al. 1991; Minamoto et al. 1994; Goto et al. 1995). The vast majority of the G protein antigenic sites seem to be conformational, sometimes involving regions that are distant from each other in the primary structure, but which are brought in proximity by protein folding and disulfide bridges. Taking into account the recent modifications in rabies epidemiology and especially the growing importance of bats in human transmission, an important effort has been done to enlarge the protection spectrum of vaccines, from anti-rabies to anti-lyssavirus status. Novel strategies have been elaborated using the versatility permitted by DNA-based immunization (Bahloul et al. 1998; Jallet et al. 1999). Plasmids expressing chimeric G proteins were constructed by fusing the COOH half of one genotype with the NH_2-half of another genotype. Upon intra-muscular injection in mice, protection was obtained against the two parental genotypes but also against other genotypes, demonstrating the possibility of increasing the spectrum from antirabies to anti-lyssavirus vaccines. Protection was also obtained by intramuscular vaccination of dogs (Perrin et al. 2000). Finally, the capability of the lyssavirus G protein to carry foreign epitopes/antigens was also demonstrated in the perspective of a future DNA multivalent vaccine against various zoonoses for carnivores (Desmezières et al. 1999).

CLINICAL AND PATHOLOGICAL ASPECTS: VESICULOVIRUS INFECTION

Vesicular stomatitis

The interest in vesicular stomatitis viruses as models for basic studies in virology and molecular biology has tended to overshadow their natural history and their role as agents of disease. The disease was first reported in livestock in the USA in 1821 (Hanson 1981). It is largely confined to the western hemisphere and reports of its occurrence elsewhere are considered to be either of importations from the West or of doubtful authenticity (Brown and Crick 1979). The virus was first isolated by Cotton (1927) and its morphology established by Chow and co-workers (Chow et al. 1954).

Disease in animals

The clinical manifestations in horses and cattle are fever, development of vesicles on the tongue, gums, and lips, and excessive salivation. Teats of milking cows may be infected and, less commonly, lesions may be seen on the feet. Animals have difficulty in eating and walking, and lose weight; milking cows stop lactating. The disease is rarely lethal except in pigs. Epizootics of vesicular stomatitis are sudden in onset (within approximately 2 weeks) and quickly involve many animals in a herd but often do not spread to adjacent farms. In the USA it occurs in the summer months in approximately 10-year cycles. In Central America, outbreaks are more frequent and possibly associated with the change from wet to dry seasons.

Disease in humans

The virus can also infect humans, usually causing a mild influenzalike illness, although more severe forms are reported. The incubation period is 1–9 days after exposure and symptoms may last 3–4 days; occasionally there may be a relapse (Sellers 1984). Infections of humans have mostly been reported in laboratory workers after aerosol inhalation or accidental contamination of eyes or abrasions. However, in some areas of North and Central

America 25–90 percent of farmers have antibody to VSV (Hanson 1981).

Transmission

The virus is found in vesicle fluid and epithelium and does not persist after recovery. It is not excreted in urine, feces, or milk. Spread by direct contact with vesicle fluid is possible, and transfer from teat lesions by milkers and milking equipment is occasionally reported. However, experimental studies have failed to demonstrate direct animal-to-animal transmission, and Sellers (1984) noted many outbreaks in which the disease did not spread to neighboring animals on the same farm. The bites of infected blood-sucking arthropods seem to be the most likely mode of transmission, demonstrated experimentally with several strains of the virus. In addition, many vesiculoviruses have been isolated in nature from mosquitoes, sandflies, midges, mites, and ticks. There are no overt pathological signs in arthropods, and how they become infected is obscure. The disease in animals being brief, with minimal and transient viremia, they are unlikely natural reservoirs of the virus. It has been suggested that some strains may be plant viruses and that animals are infected either directly, by eating infected plants, or by the bites of insects that have fed on such plants.

Vaccines

Vaccines ranging from live unmodified virus to vaccinia recombinants specific for the G protein have been used with poor success. Their development has not been pursued vigorously, both because of the self-limiting nature of the disease and because the durability of the immune response is uncertain. However, the potential of reverse genetic methods could give new perspectives in this domain (Barr et al. 2002).

CLINICAL AND PATHOLOGICAL ASPECTS: RABIES INFECTION

Although the clinical signs of rabies have been recognized for many centuries, it is mainly since the late nineteenth century that significant progress has been made in laboratory diagnosis, human postexposure treatment, control of animal rabies, and studies of the epidemiology, pathogenesis, and immune response. Currently, in most of the industrialized world, diagnostic systems are well organized, rapid, and efficient; human postexposure treatment is very effective; host species are principally wildlife; and technologically, there are excellent prospects for control or eradication of the disease in large geographical areas. In spite of these remarkable advances, rabies is still a serious problem with significant economic losses and human deaths in large parts of Africa, Asia, and South America.

Clinical aspects

FACTORS DETERMINING CLINICAL MANIFESTATIONS

The fact that not every rabid animal bite could result in clinical rabies and death has pointed out the existence of factors that could determine the clinical manifestations and lethal outcome of the disease (Hemachudha 1989). First, different species have different levels of susceptibility, latency, and infectivity (Hemachudha and Mitrabhakdi 2000). Thus, it has been possible to place species into different groups of low (e.g. opossums), moderate (e.g. nonhuman primates), high (e.g. cattle), and extremely high susceptibilities (e.g. fox) (WHO 1973). Other determinant factors are the severity of the wounds, the site of exposure, and the virus content of the saliva. For example, the incubation period is generally shorter following bite wounds to the head region than after those at the extremities, with grossly an inverse correlation between the length of the incubation period and the dose of virus. It is thought that a specific pattern of clinical manifestations could not be associated with a particular rabies virus variant, as reported by Hemachudha et al. (2003). Taken together, a combination of these factors results in the fact that the incubation period in animals may vary widely, with an usual range from 2 to 12 weeks with periods much longer than 3 months (Charlton et al. 1987), and also in the fact that in human rabies mortality after rabid animal bites varies from 35 to 57 percent (Hemachudha and Phuapradit 1997), with a few recorded cases of incubation periods of several years (Fishbein 1991; Smith et al. 1991).

CLINICAL MANIFESTATIONS IN HUMANS

Rabies is mainly transmitted through bite exposure; however, contamination can occur through aerosol, as reported in caves inhabited by rabid bats or in laboratory accidents with infected aerosolized rabid tissues. Rarely, transmission of rabies may also be associated with handling of infected carcasses, or exposure of the mucous membranes and skin abrasion to virus-laden saliva, and corneal transplantation. The transplacental route has been rarely reported in humans (Hemachudha and Mithrabhakdi 2000).

The incubation period in humans may vary from 20 to 90 days (Jackson 2003), with incubation periods as long as years that had been reported (Smith et al. 1991). The early symptoms are frequently nonspecific and may include general malaise, fever, chills, nausea, vomiting, diarrhea, headache, anxiety, apprehension, and irritability, often accompanied with itching and pruritus at the site of animal bite. After a period ranging from 2 to 10 days, neurological signs appear and the disease

may then develop according to either a furious ('encephalitic') or paralytic ('dumb') form, which may not be distinguished from magnetic resonance imaging (Laothamatas et al. 2003). Fever and proximal weakness with loss of deep tendon reflexes and urinary incontinence are universal findings. Sensory function remains intact in all modalities (Hemachudha and Phuapradit 1997).

The general features accompanying the disease are fluctuating body temperature, probably due to the effect of rabies virus infection on the hypothalamic center, myocarditis, and cerebral hypoxia due to respiratory compromise that can cause intracranial pressure, seizures, and coma (Hemachudha 1994; Warell 1976). In the furious form, signs of irritation of the central nervous system predominate, with hyperactivity (hallucinations, agitation), which can be aggravated by internal or external stimuli such as noise or light. Hydrophobia may occur in up to 50 percent of the patients (Mrak and Young 1994). Periods of hyperactivity may be interspersed with periods of calm and lucidity. Unless the patient dies early, the 'encephalitic symptoms' progress to paralysis and coma. If the disease presents as dumb (paralytic) rabies, the prodrome may be similar but the main feature is paralysis. Unless intensive care is given, patients with encephalitic rabies usually die within 7 days; those with paralytic rabies may survive as long as 2–3 weeks. A very few cases of recovery have been reported in the literature: only four patients with rabies have been reported to survive; none of them had cardinal features of rabies and were regarded as atypical rabies cases (Hemachudha and Mitrabhakdi 2000).

CLINICAL MANIFESTATIONS IN ANIMALS

It is noteworthy that most of the clinical signs of rabies are expressions of neurological dysfunctions rather than neural cell lysis (Charlton 1994). Although the clinical signs in animals are variable and may be nonspecific in the early stages of the disease, the prodromal period is generally accompanied in animals by behavioral changes. For example, during the initial prodromic phase, the dog appears as anxious and nervous (Chomel 1999) and the cat shows gait abnormality and a strange look in the eyes (Fogelman et al. 1993). Most animals become disorientated and wander aimlessly without regard for the social organization of the species.

Although there is variability in many clinical signs, the range in length of illness in most species is 1–10 days. Paralysis is fairly consistent, and is seen in nearly all cases unless death occurs early. In the dog, a furious form can be observed for 1–7 days, characterized by irritability, aggression, hypersensitivity, disorientation, and seizures (Barnes et al. 2003). In the paralytic or dumb form, which lasts 1–10 days, paralysis will affect one or more limbs, and then progresses to affect the entire nervous system, especially the cranial nerves and larynx (Chomel 1999). In horses, a predominant feature is weakness or paralysis of the hindquarters, which may be accompanied by lameness and colic (Green et al. 1992). In cattle, foamy hypersalivation and loss of appetite, voice modification, paralysis, and paresis occurred 2 days after initial signs; presence of the three major symptoms: hypersalivation, loss of appetite, and frequent mooing, should always suggest rabies infection (Chomel 1999). In wildlife, aggressive behavior is observed in up to 50 percent of the rabid raccoons, and the clinical signs are quite similar to those observed in infected skunks. In these latter, it has been shown that experimentally infected animals, after restlessness in the early stages, develop paralysis in a few days and die usually within a week (Charlton 1988, 1994; Charlton et al. 1991). Aggressive behavior has also been well documented in foxes and mongooses, which are often seen attacking domestic animals (Everard and Everard 1992). In bats, rabid animals are generally found lying on the ground, unable to fly; an experimental model of rabies virus infection has allowed to demonstrate that stable variants of the fixed rabies virus strain CVS-24 induced clinical signs such as paresis, ataxia, and inability to fly for one, whereas the second did not induce neurological signs (Reid and Jackson 2001).

Epizootiology and epidemiology

FACTORS AFFECTING THE EPIZOOTIOLOGY OF RABIES

Different species of the orders Carnivora and Chiroptera (bats) support independent epizootic cycles of different *Lyssavirus* variants. A particular species may serve as a principal host only in a limited part of its geographical distribution. The disease is transmitted regularly to a number of other mammalian species in addition to the species recognized as the principal host. The occurrence of rabies in these other species may have little or no influence on the course of an epizootic; however, their role is often not readily defined. Each principal host species has its specific pattern population biology and specific modes of social interaction. These host qualities determine which virus variants are capable of survival in this species. It is essential that an infected animal transmit the virus during a period of virus excretion to an adequate number of other susceptible individuals. For this to occur, *Lyssavirus* strains must be adapted to the physiological traits and population biology of their hosts (Bacon 1985; Wandeler 1991a; Wandeler et al. 1994). They must have a host-specific pathogenicity and pathogenesis (length of incubation period, duration and magnitude of virus excretion, duration and extent of clinical illness). We assume that each principal host has its own virus variants adapted for persistence in its populations. Thus, within the area of a principal host,

there is little virus variation among the isolates, even if they are performed in a species that is the principal host in another area. With the development of molecular and monoclonal antibody technologies it became possible to demonstrate that indeed antigenically distinct variants exhibiting phylogenetic relationships, circulate in different host populations (Rupprecht et al. 1991; Benmansour et al. 1992; Sacramento et al. 1992; Smith et al. 1992; Bourhy et al. 1993a, b; King et al. 1994; Kissi et al. 1995; Nadin-Davis et al. 1993, 1994; Nel et al. 1993; Smith et al. 1993; Tordo et al. 1993a).

TRANSMISSION OF INFECTION

Transmission of the disease usually requires bite-inflicted deposition of virus-laden saliva into tissues of the recipient animal. Virus may be excreted several days before the onset of clinical signs. The maximum recorded times are: fox, 5 days; skunk, 6 days; dog, 7 days with a Mexican isolate and 13 days with an Ethiopian isolate; cat, 3 days; bat (*Tadarida brasiliensis mexicana*), 12 days (for a review, see Charlton 1988). Excretion of virus before signs of illness is the justification for quarantine (usually 10–14 days) of clinically normal dogs and cats that have bitten humans. Occasionally, excretion of virus may be intermittent. Virus may not be isolated from glands of animals that had previously shed virus in saliva. Because of these features and the patchy nature of antigen-containing cells in salivary glands, examinations of saliva or salivary glands at the time of death may not be reliable indicators of virus transmitted in an earlier exposure to a rabid animal. There are very few data on the dose of virus received in natural infections. The carrier is defined as a clinically normal animal that secretes virus in saliva (not the immediately prodromal excretion of virus just described). There is no convincing evidence of the carrier state in field cases in North America. Most of the reports of rabies transmission by apparently healthy animals (usually dogs) and prolonged secretion in saliva are from Africa and Asia (for a review, see Fedaku 1991).

RABIES IN DOGS

One can readily distinguish between areas of the world in which dogs are the predominant hosts and those where rabies is maintained in wild animals and in which only 0.1–5.0 percent of the rabies cases reported annually are in dogs. In large parts of Asia, Africa, and Latin America, rabies in dogs is much more common, making up 95 percent or more of all diagnosed cases. Even though dog rabies is often termed 'urban rabies,' it is clearly a rural problem in many developing countries (Fedaku 1991; Bingham et al. 1999a; Wandeler and Bingham 2000). Dogs are kept and tolerated at very high numbers in most human societies, sometimes reaching densities of several thousand/km^2; this is considerably more than any wild carnivore population ever achieves (for a review, see Wandeler et al. 1993). Such high densities could facilitate enzootic canine rabies, although it is sometimes suspected that rabies in dogs is linked with wildlife rabies. There is no doubt that rabid dogs are the major source of human infection (Beran 1991). In industrialized countries of North America and Europe, where the epizootic is maintained and spread by wild carnivores, three factors may account for the low incidence of rabies in dogs: most dogs are restricted in their movements; they are kept indoors or in enclosures and leashed when outside; dog vaccination is strongly recommended or even compulsory.

RABIES IN WILD CARNIVORA

The principal rabies hosts of the order Carnivora are small- to medium-size (0.4–20 kg) omnivores, scavenging and foraging on small vertebrates, invertebrates, fruit, and refuse produced by humans. They reach high population densities (often several individuals/km^2) in and near human settlements. High intrinsic population growth rates allow rapid recovery of populations reduced by persecution or disease. They are all able to support initial epidemics of high case density and thereafter an oscillating prevalence over many years (Wandeler 1991a).

Areas for which associations of RABV variants with populations of wild Carnivora are well documented are limited to North America, Europe, parts of southern Africa, and some Caribbean islands. The red fox (*Vulpes vulpes*) is the principal rabies host in subarctic and northeastern North America, in all of central and eastern Europe, and in subarctic and temperate zones of Asia (Blancou et al. 1991). In arctic regions of North America and Asia, the arctic fox (*Alopex lagopus*) is the predominant rabies host (Crandall 1991). The viruses isolated from red and arctic foxes from fox rabies areas of North America are all closely related, but distinct from European fox isolates. Jackals (*Canis* spp.) are the principal hosts in southern Africa (Foggin 1985; Bingham et al. 1999b) and are probably involved in much larger areas in Africa and Asia. Other wildlife species that maintain independent cycles of distinct RABV variants in southern Africa are various viverrids, especially the yellow mongoose (*Cynictis penicillata*), and possibly the bat-eared fox (*Otocyon megalotis*) (King et al. 1994). The striped skunk (*Mephitis mephitis*) is the species most often diagnosed rabid in large areas of Canada and the USA (Charlton et al. 1991). Raccoon (*Procyon lotor*) rabies is at present confined to the USA, but is spreading in the southeastern and in mid-Atlantic states (Winkler and Jenkins 1991). Mongooses (*Herpestes auropunctatus*) introduced to some Caribbean islands are now the principal reservoir there (Everard and Everard 1985). Gray foxes (*Urocyon cinereoargenteus*) in some North American areas (Carey et al.

1978) and raccoon dogs (*Nyctereutes procyonides*) introduced to eastern and subarctic Europe (Cherkasskiy 1988) are sometimes suspected of supporting independent epizootics.

RABIES IN BATS

The African bat *Lyssavirus* isolates are of genotypes (serotypes) 2 and 4, while those from bats in Europe were identified as genotypes 5 and 6. Isolates from Australian Megachiroptera and from insectivorous bats are called Australian bat lyssaviruses. They form a distinct clade (genotype 7) in phylogenetic analysis (for a review, see McColl et al. 2000). American bat rabies viruses have been categorized as genotype 1, but a more detailed analysis of the large diversity of distinct isolates offers some surprises. Chiroptera have life history traits that are quite different from those of carnivorous rabies hosts: they are small, long-lived, have low intrinsic population growth rates, and are ecological specialists. The properties of lyssaviruses adapted to bats must therefore be different from those of Carnivora rabies. This statement remains a hypothesis because the population biology and epidemiology of bat rabies is insufficiently explored. A notable exception is rabies in vampire bats as described by Lord et al. (1975). An interesting feature of bat rabies is the vast antigenic diversity of isolates. In Canada alone, 12 distinct variants are recognized with mAbs. Several variants occur in a single species, and the geographical distribution of variants is overlapping (Nadin-Davis et al. 2001). This is in sharp contrast to the pattern of rabies in Carnivora, where very little epitope variation is recognized over very large areas (Nadin-Davis et al. 1999).

INCIDENCE OF RABIES IN HUMANS

In industrialized countries, rabies in humans is rare owing to low rates of exposure, high standards of health education and relatively easy access to postexposure treatment with potent vaccines. However, an estimated 35 000–60 000 people die from rabies every year worldwide. The number of people receiving postexposure treatment – mostly after dog bites – is about 3.5 million per year (Bögel and Motschwiller 1986; Bögel and Meslin 1990). Almost all deaths of humans from rabies and the vast majority of treated bite exposures occur in developing countries (Acha and Arambulo 1985). This may in part be due to a high rate of exposure to biting rabid dogs, but even if this assumption is correct, it does not fully explain the high number of rabies casualties. In view of the efficacy of modern postexposure treatment, nearly all cases of rabies in humans must be considered as failures of the medical system. For various reasons, including lack of availability or ignorance, the correct treatment was not applied or not applied in time (Wandeler et al. 1993).

PATHOGENESIS AND PATHOLOGY

Rabies virus spread

INOCULATION SITE

After contamination, it has been shown that rabies virus might infect the cells located within the site of inoculation, generally the myocytes (Figure 8) (Murphy et al. 1973; Charlton and Casey 1979). The data are confirmed by in vitro models of infection of cultured myotubes, where infection and replication of street rabies virus can be demonstrated (Tsiang et al. 1986). These data can provide an explanation for the long incubation that can be observed during natural rabies virus infection (Charlton et al. 1997). However, classical experiments have shown that in some cases rabies virus was able to leave the site within a few hours following inoculation, in agreement with a mouse model of infection where direct infection of the nerve endings without prior replication in the muscle has been demonstrated (Shankar et al. 1991).

VIRUS SPREAD TO THE CENTRAL NERVOUS SYSTEM

Whichever are the first host cells to be infected, rabies virus enters both sensory and motor fibers (Coulon et al. 1989; Lafay et al. 1991) probably through a receptor-mediated endocytosis (for the putative receptors see section on Epizootiology and epidemiology above). Studies in cultured neuronal cells indicate that after entry in axon terminals (or somatodendritic domain), rabies virus can be detected in endosomes shortly after uptake (Lewis and Lentz 1998; Lewis et al. 1998).

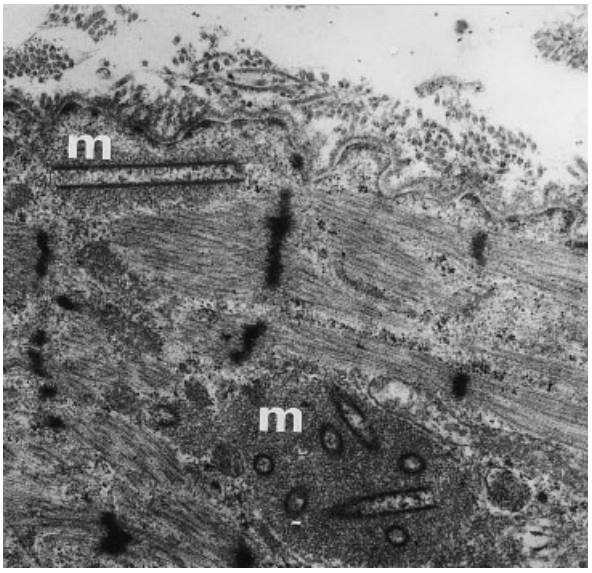

Figure 8 *Electron micrograph of two bodies of matrix (m) and anomalous tubular structures in a muscle cell of a skunk at the site of inoculation of street RABV (×2 000).*

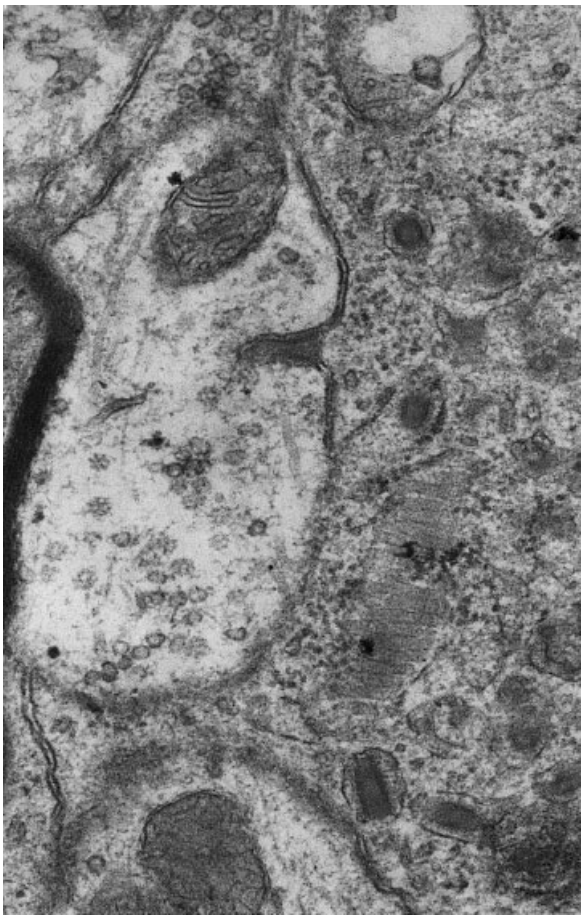

Figure 10 *Electron micrograph of skunk brain. Virion budding on neuronal plasma membrane and simultaneous endocytosis by an adjacent axon terminal (×25 000).*

Rabies virus is then transported through axonal transport in the peripheral nervous system toward the central nervous system. This transport is dependent on the microtubule network, as shown by inhibition produced by microtubule-disrupting colchicine and vinblastine (Bijlenga and Heany, 1978; Tsiang 1979). By using cultured sensory neurons in two-compartments devices, it has been demonstrated that rabies virus used the retrograde axonal transport to disseminate within the neuron, at a rate of 25–50 mm/day at least, which is compatible with a fast microtubule-based retrograde transport (Lycke and Tsiang 1987; Tsiang et al. 1991). These properties of rabies virus have been used for retrograde transneuronal tracing studies within the peripheral nervous system (Tang et al. 1999) (Figures 9 and 10).

SPREAD WITHIN THE CENTRAL NERVOUS SYSTEM

Once rabies virus has reached the spinal cord or brainstem neurons, it disseminates rapidly throughout the central nervous system. Analysis of postmortem brains of naturally infected humans indicate that almost all the brain areas may be infected: thalamus, spinal cord, pons, medulla oblongata, cerebellum, hippocampus, and striatum (Bingham and van der Merwe 2002; Vural et al. 2001). Rabies virus replication occurs primarily in the neurons (Tsiang et al. 1983; Gillet et al. 1986; Kelly and Strick 2000), although some rabies virus strains in some species have been reported to be able to infect significantly other neural cells, such as Bergmann glia (Jackson et al. 2000). The spread of rabies within the central nervous system occurs from neuron to neuron by combination of axonal transport and transsynaptic passage.

The transsynaptic passage has been studied by stereotactic inoculation experiments in the rat (Gillet et al. 1986; Ceccaldi et al. 1989), which have shown that rabies virus uptake occurs mainly at the axon terminal, following the neuroanatomical connections. This is compatible with electron microscopy studies in the skunk, showing viral budding at the postsynaptic membrane (Charlton and Casey 1979). The viral glycoprotein G is required for this transsynaptic transfer (Etessami et al. 2000) and is responsible for the diverse

distribution patterns of the different rabies virus strain in the brain (Yan et al. 2002).

The retrograde axonal transport of rabies virus in the brain has also been demonstrated by stereotactic inoculation experiments (Gillet et al. 1986; Ceccaldi et al. 1989; Etessami et al. 2000) and by neuroanatomical studies (Kucera et al. 1985). More recently, the retrograde axonal transport, transsynaptic transfer and its low cytopathic effect of rabies virus has been used for neuroanatomical tracing studies within the monkey brain (Kelly and Strick 2000). Rabies virus transport within the central nervous system is dependent on the integrity of the microtubule network (Ceccaldi et al. 1989; Ceccaldi et al. 1990). In the past few years, the molecular basis for axonal transport of rabies virus has been extensively studied since two independent groups demonstrated a strong interaction between the rabies virus phosphoprotein P and the light chain (so-called LC8 of the cytoplasmic dynein) (Jacob et al. 2000; Raux et al. 2000). These results are confirmed by reverse genetic studies showing that abolishing the P–LC8 interaction by deletion of the conserved LC8-interacting motif (K/RXTQT) in the rabies virus phosphoprotein P is able to reduce the efficiency of peripheral spread of an attenuated rabies virus strain SAD D-19 (with replacement at the Arg at position 333) (Mebatsion 2001). However, this deletion has no effect in intracranial inoculation, suggesting that other mechanisms could act together with P–LC8 interaction for rabies virus spread, although recombinant *P*-gene-deficient rabies viruses are apathogenic in adult and suckling mice, even when inoculated intracranially (Shoji et al. 2004).

Events within the central nervous system

HISTOPATHOLOGY

Relatively mild neuropathological changes are generally observed in the central nervous system of infected hosts (Iwasaki and Tobita 2002), and neuronal cell death does not seem to be prominent during the course of rabies (Ceccaldi 1999; Jackson 2003; Kelly and Strick 2000). However, according to the viral strains that are concerned, mild to severe histopathological can be observed, although they are not constant. They can vary from moderate perivascular cuffing with mononuclear cells (Foley and Zachary 1995), focal and regional gliosis, slight neuronophagia, and presence of inflammatory cells in the meninges (Charlton 1988; Perl and Good 1991) to extensive neuronal degeneration and neuronophagia, associated with widespread inflammation (Fekadu et al. 1982).

Spongiform lesions in rabies were first described by Charlton (1984) in experimentally infected skunks and red foxes, and were further found in natural infections and in other species (Foley and Zachary 1995). The

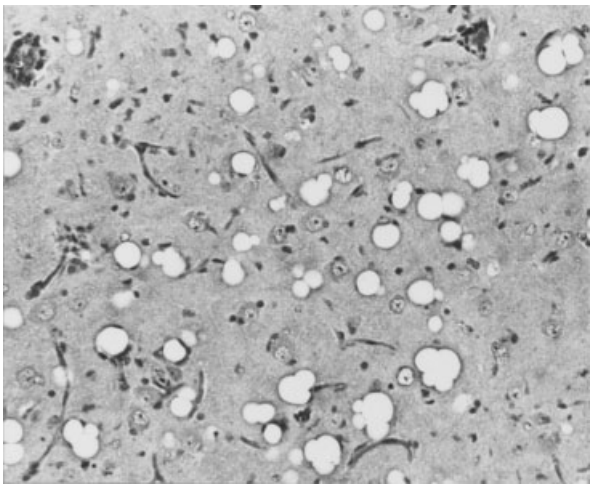

Figure 11 *Spongiform lesions in neurophil of thalamus of a skunk experimentally infected with street RABV (H & E, ×160) (reproduced, with permission of the publisher, from Charlton 1984).*

thalamus (all nuclei) and cerebral cortex are the most frequently and severely affected regions (Figure 11). Vacuolation seems to develop rapidly, probably in <2–3 days, occurs after infection by several street virus variants, and is independent of the immune response, route of inoculation, or viral preparation (Charlton et al. 1987) (Figure 12). In affected regions of the brain, the degree of vacuolation was not correlated with the amount of antigen accumulation, suggesting that spongiform change in rabies is probably an indirect effect, such as neurotransmitter imbalance.

NEURAL DYSFUNCTIONS

The fact that brain damage may be relatively limited and that neuronal death is not pronounced during rabies

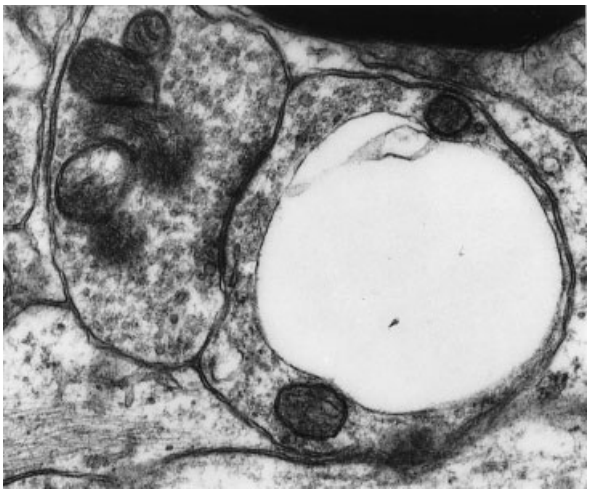

Figure 12 *Electron micrograph of a membrane-bound vacuole in the dendrite of a neuron in skunk brain (×30 000) (reproduced, with permission of the publisher, from Charlton 1984).*

has rapidly led to the hypothesis that rabies disease would be mostly due to neural dysfunction rather than neuronal cell lysis (Tsiang et al. 1983; Jackson 2002). Clinically, some data have been provided recently by magnetic resonance imaging of the brain where some patients show multifocal lesions in the brainstem and hypothalamus, with high signals on T2-weighted images in the medulla, pontine tegmentum, and hypothalamus (Pleasure and Fischbein 2000). Experimentally, it has been shown that rabies virus was able to alter the neuronal physiology at different levels, in cultured neural cells as well as in murine models. These alterations concern the release and uptake of neurotransmitters, as shown for GABA whose uptake is reduced (45 percent) in rabies virus-infected cells (Ladogana et al. 1994), or serotonin release (Bouzamondo et al. 1993). Changes in the number of receptors to neurotransmitters have also been described (Ceccaldi et al. 1993). Abnormalities are also detected in the modulation of neural receptors, such as α2-adrenoreceptors whose modulation is prevented by rabies virus, but not muscarinic receptors, of Ca^{2+} channels in neuroblastoma cells (Iwata et al. 2000). Nitric oxide neurotoxicity has been hypothesized to mediate neuronal dysfunction in rabies, since induction of inducible nitric oxide synthase mRNA and increased quantities of nitric oxide in brains of experimentally infected rodents have been reported (Koprowski et al. 1993; Hooper et al. 1995). Interestingly, inducible nitric oxide synthase inhibition is able to delay death of rabies virus-infected mice (Ubol et al. 2001).

More recently, regulation of neuronal gene expression has been described in experimentally infected murine models of rabies virus. These works report activation of immediate–early genes mRNA expression (correlated with an increase in rabies RNA (Fu et al. 1993), up-regulation of nine genes during rabies virus infection (Egr1, STAT1) (Saha and Rangarajan 2003) and dysregulation of expression of 39 genes during infection; these included genes involved in regulation of cell metabolism, protein synthesis, synaptic activity, and cell growth and differentiation (Prosniak et al. 2001).

APOPTOSIS

Apoptosis can be observed during rabies infection both in vivo in mice (Thoulouze et al. 1997), and in virus-infected mouse neuroblastoma cells which undergo chromatin condensation and DNA fragmentation within 48 h postinfection (Ubol et al. 1998). Interestingly, a bat strain and a primary canine rabies virus isolate were both able to induce apoptosis in infected mice and reactivate a developmentally down-regulated gene, *Nedd-2*, which may be required for apoptotic elimination of cells damaged by infection (Ubol and Kasisith 2000). Apoptosis could play a role during nonfatal rabies infection, where the levels of viral replication and primary degeneration of infected neurons by apoptosis could be responsible for the infiltration of T lymphocytes capable of inducing secondary degeneration of neural cells (Galelli et al. 2000). The pro-apoptotic properties of the different virus strains being dependent on the viral glycoprotein G (Préhaud et al. 2003) as well as matrix protein M (Kassis et al. 2004).

However, the fact that a silver-haired bat rabies virus variant does not induce apoptosis in the brain of experimentally infected mice suggests that apoptosis would not be an essential pathogenic mechanism for the outcome of a rabies virus infection. Furthermore other pathological processes may contribute to the profound neuronal dysfunction characteristic of street rabies (Yan et al. 2001), although numerous apoptotic neurons could be identified in the brain stem and hippocampus of the brain of a rabies- (and HIV-)infected patient (Adle-Biassette et al. 1996).

PERIPHERAL SPREAD OF VIRUS AND INFECTION OF NONNERVOUS TISSUE

While rabies virus disseminates and replicates within the central nervous system, a subsequent viral transport to peripheral tissues occurs. This transport allows infection of nonnervous tissues such as muscle, myocardium, kidney, lung, pancreas, and lacrymal glands. In a study performed in 11 human rabies confirmed cases, it has been shown that rabies virus antigens could always be found in the adrenal glands, heart, pancreas, and gastrointestinal tract (Jogai et al. 2002). In a murine experimental model of infection, Tsiang demonstrated that the mechanism for such a centrifugal spread was microtubule dependent and involved the axonal transport (Tsiang 1979). The infection of salivary glands is of particular relevance to further transmit the disease for many species (Figures 13 and 14).

IMMUNE RESPONSES

An important concern is the extent to which the expressions of the naturally occurring disease are the result of the immune response. Although conclusive evidence from natural infections is rather sparse, several reports of experimental studies suggest that the immune response can influence the susceptibility, incubation, and morbidity periods, the type of clinical signs, excretion of virus, and recovery from infection (before or, rarely, after clinical signs). In addition, these effects frequently depend on interactions of the immune response with other factors, such as animal species and age, viral strain, route of inoculation, and dose of virus.

NEUTRALIZING ANTIBODIES

Virus-neutralizing antibodies (VNA) are a critical component of immune resistance. They are produced in response to RABV glycoprotein; production is T-cell dependent, requiring $CD4^+$ T cells, as well as B cells. They are considered to be most effective in the early

Figure 13 *Electron micrograph of rabies virions in acinar lumen of submandibular salivary gland (skunk) (×30 000).*

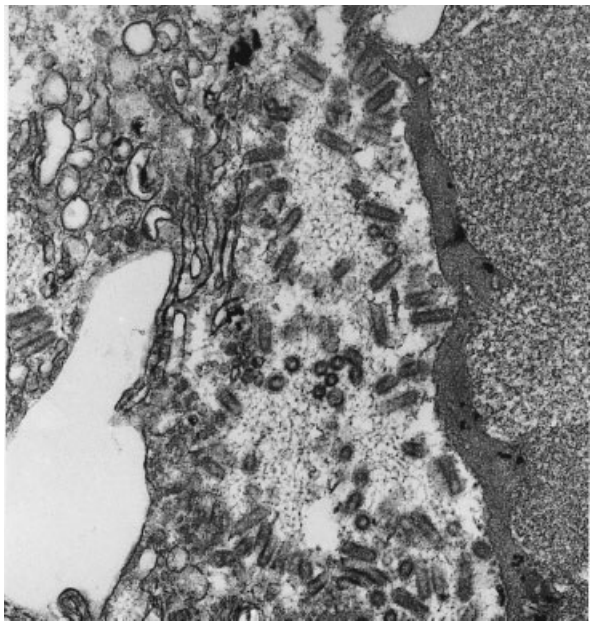

Figure 14 *Electron micrograph of mucous cell of submandibular salivary gland of skunk infected with street RABV. Viral budding on the inner surface of secretory granules (×37 500).*

stages of infection, i.e. before viral entrance into peripheral nerves. However, some weakly pathogenic strains can be cleared from the central nervous system (CNS) by VNA. Apparently, protection resides primarily with IgG rather than IgM (for reviews, see Turner 1990; Lafon 1994). Measurement of serum VNA has been and continues to be the predominant method for estimating immune resistance to rabies infection in humans, and in conjunction with challenge is frequently used in efficacy tests of vaccines in other animals.

Generally, VNA is not detected in infected humans until after the onset of clinical signs (for reviews, see Fishbein 1991; Hemachudha 1994). In animal experiments, the relation of neutralizing antibody to outcome of infection is variable. There are several reports of VNA in a small proportion of apparently healthy foxes, skunks, and raccoons in rabies enzootic areas, presumably because of previous exposure to the virus (for reviews, see McLean 1975; Winkler 1975; Blancou et al. 1991; Winkler and Jenkins 1991; Wandeler et al. 1994). The prevalence of VNA in mongooses in enzootic areas in Grenada may be high (up to 40 percent), and fluctuates with changes in the incidence of rabies. High titers of VNA may be indicative either of advanced CNS infection or of recovery. Evidence that the VNA response can influence susceptibility to rabies comes mainly from work with inbred strains of mice inoculated intraperitoneally with street RABV (for review, see Lodmell 1988): resistant and susceptible strains were, respectively, good or poor responders in terms of VNA production.

N PROTEIN

Recent advances include the demonstration, originally by Dietzschold and co-workers (1987), that N protein can induce an immune response sufficient to protect animals against challenge in the absence of detectable VNA. Priming with N protein can augment the production of VNA on subsequent inoculation of live vaccines (for review, see Fu et al. 1994). A recent study indicates that the nucleoprotein of RABV is a superantigen (Lafon et al. 1992). The significance of this in immune resistance has not yet been determined (Lafon 1994).

IMMUNOSUPPRESSION AND CELL-MEDIATED IMMUNITY

Various features of rabies have been studied by immunosuppression or other manipulations of immune mechanisms in experimental animals. The findings include an increase or a decrease in the incubation period due to immunosuppression (Tignor et al. 1974; Smith et al. 1982; Charlton et al. 1984); early death in mice due to antibody and not to immune T cells (Prabhakar and Nathanson 1981); optimum clearance of RABV from the nervous system requires both B and T lymphocytes (Kaplan et al. 1975; Miller et al. 1978; Prabhakar et al. 1981; Smith 1981); immunosuppression-facilitated centrifugal neural

migration of virus (Smith et al. 1982); and dissemination to the salivary glands (Charlton et al. 1987).

Cytotoxic T cells can be induced by rabies glycoprotein, nucleocapsid, N protein, and NS protein (for review, see Lafon 1994). The precise role of cytotoxic T cells in immunoprotection has not been resolved. Under certain circumstances, they may be critical for host defense (Nathanson and Gonzalez-Scarano 1991). Lafon (1994) has indicated that, in the absence of neutralizing antibodies, cytotoxic T cells are not sufficient to protect the host; however, their participation in combination with other immune effector mechanisms cannot be excluded. Alternatively, they may contribute to immune injury in rabies.

INFLUENCE OF IMMUNE RESPONSE ON TYPE OF RABIES

The role of the immune response in the type of clinical signs, especially encephalitic versus paralytic rabies, is now being studied. As described above, in skunks inoculated with street virus, early spread in the CNS included ventral motor neurons in the lumbar cord, the motor cortex, and other brain nuclei relevant to motor control of skeletal muscle. Assuming its deleterious effect on infected neurons, an early immune response might be more likely to induce paralytic rather than encephalitic signs. In fact, several studies do support a role for the immune response in paralytic rabies (Tignor et al. 1974; Iwasaki et al. 1977; Smith et al. 1982; Sugamata et al. 1992; Weiland et al. 1992; Lafon et al. 1994). However, Hemachudha et al. (1988) suggested that in humans, lymphocyte proliferative responses are associated with encephalitic rabies, and that paralysis in mice infected with the CVS strain of RABV did not depend on the T-cell system (Hovanessian et al. 1988). Still other studies suggest that the immune response has little effect on the type of clinical signs (Gourmelon et al. 1991; Charlton 1994).

Diagnosis

Rabies diagnosis serves epidemiological surveillance, the monitoring of disease control efforts, and to educate postexposure prophylaxis (PEP) in exposed people. Because almost all human infections result from bites by rabid animals, the decision to initiate or continue PEP often depends on the results of laboratory diagnostic tests on the animal of concern. Diagnostic programs require efficient and well-organized field inspection, specimen collection, and submission systems, adequately equipped laboratories and well-trained laboratory personnel, and effective reporting systems. Details of the laboratory procedures are contained in several excellent reviews (Webster and Casey 1988; Sureau et al. 1991; Trimarchi and Debbie 1991; Bourhy et al. 1992; Meslin et al. 1995).

NEGRI BODIES

The inclusion bodies discovered by Negri (1903) in the cytoplasm of rabies-infected neurons served as exclusive pathognomonic lesions for half a century until immunofluorescence methods were introduced in the late 1950s and early 1960s (Goldwasser and Kissling 1958). The Negri body methods are rapid, but there is a fairly high rate of false negatives (10–20 percent) when compared to antigen detection by immunofluorescence or virus isolation.

IMMUNOFLUORESCENCE

During the 1960s, the fluorescent antibody test (FAT) rapidly became the method of choice. The method can be performed on smears of brain tissue, produces results in a few hours, and, most importantly, is highly specific. With improvements in conjugates and microscopes, the rate of false-negatives has gradually decreased to about 0.1 percent. Most laboratories use immunofluorescence as a primary test. It is recommended that negative FAT results on brains from animals with a history of human exposure be subjected to a confirmatory test, such as a cell culture or mouse inoculation test.

MOLECULAR BIOLOGICAL TECHNIQUES

The 1992 WHO Expert Committee on Rabies did not recommend PCR for routine rabies diagnosis because of the obvious difficulties in preventing cross-contaminations in diagnostic laboratory settings. However, molecular techniques are becoming rapidly more accessible and sophisticated and have potential for diagnostic applications (Sacramento et al. 1991; Tordo et al. 1992b, 1995; Kamolvarin et al. 1993), particularly for antemortem confirmation of suspect human cases (Tordo et al. 1995) and for material that is not suitable for FAT.

OTHER METHODS

The rapid rabies enzyme immunodiagnosis (RREID) test has a high degree of accuracy, and has been advocated for laboratories (e.g. in developing countries) having difficulties in using the FA test, and for screening large numbers of specimens in epidemiological studies. It can be performed on heat-inactivated specimens but not on formalin-fixed specimens. Immunohistochemical (immunoperoxidase) methods and in situ hybridization (Nadin-Davis et al. 2003) are suitable when only formalin-fixed specimens are available.

Antemortem diagnosis is occasionally requested for humans with suspected rabies. Corneal impressions and skin biopsies (back of the neck above the hairline) are recommended for immunofluorescence and oral fluids for virus isolation and PCR detection of viral RNA.

IDENTIFICATION OF VIRUS VARIANTS

Molecular analysis has largely replaced serological methods for the classification of viruses. The character-

ization of selected parts of viral genomes permits reconstructing evolutionary relationships. These can be displayed as phylogenetic trees. Likelihood values can be calculated for different conceivable branching topologies. Molecular epidemiology is the reconstruction of the history of an epidemic using these powerful tools (Nadin-Davis et al. 1999). Monoclonal antibodies recognize phenotypic aspects of viral proteins and can therefore not provide phylogenetic information with the same accuracy. However, they bind to molecular surface structures recognized by a host's immune system, structures that are likely to have functional properties on which natural selection may act. While molecular studies remain fairly laborious and costly processes, the antigenic characterization with mAbs is an inexpensive 'workhorse' approach to identify large numbers of virus isolates in a diagnostic laboratory setting. Though the binding of a larger number of mAbs can be studied on infected cell cultures, it is important that the tests can be conducted on the original brains in order to remain low in cost and efforts. A panel of mAbs must discriminate between the different species and variants occurring in an area. Variants should be defined as members of a clade (branch) in a phylogenetic tree.

Control

The ultimate purpose of rabies control is the protection of humans from both infection and economic loss. In humans, rabies can be controlled by prophylactic vaccination and postexposure treatment, by reducing the risk of human exposure, or, conclusively, by eradication.

CONTROL OF RABIES IN DOMESTIC ANIMALS

Control measures may include immunization, movement restrictions, reproduction control, habitat control, and removal of stray dogs (Wandeler and Bingham 2000; Meslin et al. 2000).

Immunization

An effective way of reducing the incidence of human infection is by prophylactic immunization of those domestic animals that are the most common sources of human exposure. Rabies has a high incidence in dogs in enzootic areas where dog populations reach high densities. Well-planned and -executed vaccination campaigns drastically reduce rabies incidence in dogs and may even eliminate the disease in areas where it is not maintained by wildlife. Elimination of the disease should be the goal rather than a temporary reduction in incidence. The most economical way to achieve it is by mass vaccination performed in accordance with a comprehensive national plan. Vaccinations should be done by parenteral inoculation of a product approved by the national authorities, usually an inactivated vaccine conferring 2 years of immunity after one injection. When the appropriate technology and resources are available, the immunization of individual domestic animals should be verifiable by certification, preferably in the form of an implanted microchip.

Whenever possible, modern inactivated cell culture vaccines should be used for the immunization of dogs and other domestic animals. They combine safety with high immunogenicity. Cell lines and primary cell cultures are used as substrates for a number of different virus strains. Several manufacturers include a variety of different antigens (distemper, adenovirus, leptospirosis, parainfluenza, parvovirus) in combined vaccines. The use of live-attenuated vaccines is no longer recommended for dog immunization, except for special situations (e.g. national campaigns under economic constraints). Live recombinant vaccines and other products of genetic engineering are now becoming available.

Quarantine

Many countries have legislation for destroying or quarantining for several weeks domestic animals after possible contact with a suspect animal. A ten-day quarantine is recommended for dogs and cats that have bitten a person. The quarantined animal is killed and submitted for laboratory diagnosis if it develops suspicious symptoms during this observation period.

A number of countries that are free from rabies in wild carnivores and dogs have prevented the importation of terrestrial mammal rabies by rigorous enforcement of quarantine measures; for example, a 6-month quarantine period for imported cats and dogs in the UK. This approach is now considered unnecessary, given the availability of effective vaccines for pet animal immunization and tests for verifying an adequate antibody response.

IMMUNIZATION OF WILD ANIMALS

Control of wildlife rabies by reducing population densities of host species has been attempted repeatedly. However, the resilience of these opportunistic Carnivora to persecution, their reproductive potential, and high carrying capacities of both rural and urban habitats often nullify such efforts. A more promising approach is mass vaccination of the main hosts. Immunization of free-living wild animals is not an easy task. The wild mammal has to be lured into vaccinating itself. The methods have to be simple and efficient, so that it becomes technically and economically possible to establish the herd immunity required to eliminate rabies. Oral rabies immunization became attainable in the early 1970s when it was found that ingested attenuated rabies vaccine, ERA, immunized foxes (Black and Lawson 1970; Baer et al. 1971). This discovery suggested the possibility of administering an oral rabies vaccine to wild carnivores by bait.

Wandeler (1991b) detailed the requirements for vaccines to be used for oral immunization of free-living wild animals. Currently only live-attenuated or live recombinant vaccines are available for oral immunization. They have to infect host cells for eliciting a protective immune response. A high residual pathogenicity is a severe weakness of the initially applied ERA/SAD vaccines. The most important qualities of baits for proper vaccine delivery are that they should, as far as possible, be attractive for the target species and not for others. The delivery system must ensure mass immunization of the target species. Technical resources, administrative structures and labor needs, as well as constraints imposed by safety requirements, terrain, climate, etc., have to be taken into account.

The development of oral immunization of wildlife as an instrument for rabies control has been described by Winkler (1992). Aubert et al. (1994) have reported the extent of wildlife rabies vaccination in Europe, and Campbell (1994) has given an account of the North American situation. The first field trial with foxes was carried out in Switzerland in 1978 (Steck et al. 1982). Most areas in Switzerland and later, large areas of other European countries and Canada became free from rabies after oral immunization campaigns with ERA/SAD vaccines. Newer genetically engineered recombinant vaccines have great potential for wildlife rabies control (Blancou et al. 1986; Rupprecht et al. 1986; Yarosh et al. 1996). A vaccinia–rabies glycoprotein recombinant (V–RG) has been used successfully in Belgium (Brochier et al. 1991), Luxembourg, and in parts of France (Aubert et al. 1994). V–RG is applied in North America in attempts to control rabies in raccoons (Robbins et al. 1998), coyotes, and gray foxes.

The most important conclusion from the field applications of oral vaccination is that it appears to be possible to immunize sufficient host individuals to stop the spread of the disease into rabiesfree areas and to eliminate it from enzootic areas in terrestrial mammals. In Europe, rabies did not reappear spontaneously from an undetected reservoir after fox vaccination campaigns were discontinued, but was occasionally able to reinvade a fox population from infected contiguous areas. However, caution has to be applied when interpreting prevalence data from field studies that have no adequate controls and that cannot be repeated (Wandeler 2000).

RABIES PROPHYLAXIS IN HUMANS

The history of rabies vaccines and of postexposure treatment in humans from the time of Louis Pasteur to the modern era has been well described (Vodopija and Clark 1991; Thraenhart et al. 1994). Highly efficacious vaccines that usually provoke only minimal or no side effects are now available and can be used for pre- and postexposure immunization. All of them contain RABV antigens in a concentrated and partially purified form. Preparations widely used are the human diploid cell strain (HADES) or the Vero cell strain, which are inactivated with β-propiolactone. Unfortunately, because of economic considerations, the cheaper brain tissue-derived vaccines are still predominant in large parts of the world. These vaccines are of inferior potency and may induce severe allergic reactions that can occasionally be difficult to distinguish from clinical rabies (Hemachudha 1989).

Pre-exposure prophylaxis

Pre-exposure immunization is generally encouraged only for people at potentially high risk of exposure; for example, laboratory personnel working with rabies, veterinarians, and animal control and wildlife officers. Pre-exposure immunization consists of a series of inoculations (usually three) within 21–180 days with an approved and potent inactivated vaccine. Serum antibody titers should be monitored. For people at continuing high risk of exposure, it is recommended that booster injections are given when the serum antibody titer falls below 0.5 IU/ml (WHO 1992).

Postexposure prophylaxis

People bitten or licked by a mammal acting abnormally in a geographic area where rabies might occur must be considered as exposed and postexposure treatment should begin as soon as possible. Properly administered, it is highly effective. It consists of passive immunization with rabies immunoglobulin, and vaccination (WHO 1992). Instant thorough washing of bite and scratch wounds with water and soap or detergent is most important; the use of disinfectants is also recommended. Purified rabies immunoglobulin, of equine or, preferably, human origin (HRIG), and the first dose of a potent vaccine must be administered with as little delay as possible. Additional doses of vaccine at the officially specified intervals are necessary. Tetanus prophylaxis should also be given to people without definite evidence of recent immunization. Recommendations on what has to be considered an exposure, what vaccines to use, routes of vaccine administration, treatment schedules, and the application of immunoglobulins vary from country to country; the guidelines of the national health authority must be consulted.

Borna disease virus

THOMAS BRIESE, MADY HORNIG, AND W. IAN LIPKIN

General features	1	Vaccines and antivirals	17
Molecular biology of BDV	1	References	17
Pathogenesis and epidemiology of BDV	6		

GENERAL FEATURES

Borna disease virus (BDV) is the prototype of the family *Bornaviridae*, genus *Bornavirus*, within the nonsegmented, negative-strand (NNS) RNA viruses (order *Mononegavirales*). The name Borna refers to the city of Borna, Germany, which was the site of an equine epidemic in 1895–1896 that crippled the Saxon cavalry. This neurotropic virus appears to be distributed worldwide and has the potential to infect most, if not all, warmblooded hosts. At the time of writing it is the only known example of the family *Bornaviridae*. BDV is similar in genomic organization to other NNS RNA viruses; however, its genome (about 8.9 kb) is substantially smaller than those of *Rhabdoviridae* (about 11–15 kb), *Paramyxoviridae* (about 15–16 kb) or *Filoviridae* (about 19 kb), and BDV is distinctive in its nuclear localization of replication and transcription. Although this feature is shared with the plant nucleorhabdoviruses (Martins et al. 1998), it is unique among NNS RNA animal viruses. Genome organization and gene expression of BDV are remarkable for the overlap of open reading frames (ORF), transcription units, and transcription signals; readthrough of transcription termination signals; and differential use of translation initiation codons. There is precedent for the use of each of these strategies by the *Mononegavirales*. The concurrent use by BDV of such a diversity of strategies for the regulation of its gene expression is unprecedented in NNS RNA viruses. Furthermore, BDV uses the cellular splicing machinery to generate some of its mRNAs. Although splicing is found in *Orthomyxoviridae* (segmented, negative-strand RNA viruses), it is novel in an NNS RNA virus.

Virion molecular weight and the $S_{20,\omega}$ are not known. Partially purified BDV infectious particles have a buoyant density in CsCl of 1.16–1.22 g/cm^3, in sucrose of 1.22 g/cm^3, and in renografin of 1.13 g/cm^3. Virions are stable at 37°C and lose only minimal infectivity after 24 h of incubation in the presence of serum. Virus infectivity is rapidly lost by heat treatment at 56°C, exposure to pH 5.0, organic solvents, detergents, chlorine, formaldehyde, or UV radiation (Ludwig et al. 1988). Several complete genomic BDV sequences are now reported, including strain V (Briese et al. 1994), He/80 (Cubitt et al. 1994a), CRNP5 (a rat-passaged strain with altered pathogenicity) (Nishino et al. 2002), and No/98 (Nowotny et al. 2000; Pleschka et al. 2001). No/98, an Austrian isolate, is unusual in that it differs from other isolates by more than 15 percent at the nucleotide level; other known BDV isolates, including those where only partial sequence data are available, differ generally by less than 6 percent.

MOLECULAR BIOLOGY OF BDV

BDV genome organization

Independent cloning experiments in two laboratories, using either ribonucleoprotein (RNP) preparations or viral particles obtained from infected cultured cells with high salt release techniques, revealed a negative-polarity single-stranded RNA genome comprising approximately 8.9 kb (Briese et al. 1994; Cubitt et al. 1994a). The BDV genome is remarkably compact, encoding six major ORFs in three transcription units

framed by complementary termini similar to those of other NNS RNA viruses (Figure 1) (Briese et al. 1994; Wehner et al. 1997). The first transcription unit reveals a simple pattern with only one coded protein (nucleoprotein, N, p38/40). The second transcription unit encodes proteins X (p10) and P (phosphoprotein, p23) in overlapping ORFs. The third unit contains coding sequence for the matrix protein (M, p16), type I membrane glycoprotein (G, p57, gp94), and polymerase (L, p190). Elaboration of these proteins is dependent upon a variety of mechanisms for transcriptional, posttranscriptional, and translational control of expression, including alternative transcriptional initiation, readthrough of termination signals, splicing, and leaky ribosomal scanning (reviewed in Schneemann et al. 1995).

Replication and transcription

Replication and transcription of the BDV genome occur in the cell nucleus. Although nuclear replication and transcription are found in segmented negative-strand RNA viruses and nucleorhabdoviruses (NNS RNA viruses of plants), BDV is the only NNS RNA virus of animals with this property (Briese et al. 1992).

The 5′ and 3′ terminal nontranscribed sequences of NNS RNA viruses typically encode promoters that serve for both replication and transcription of the genome. BDV contains a 42 nucleotide untranslated region (UTR) at the 3′ end of the genome, which presumably functions as a promoter for expression of the viral (+) sense antigenome and viral transcripts, and a 54 nucleotide UTR at the 5′ end, presumably initiating

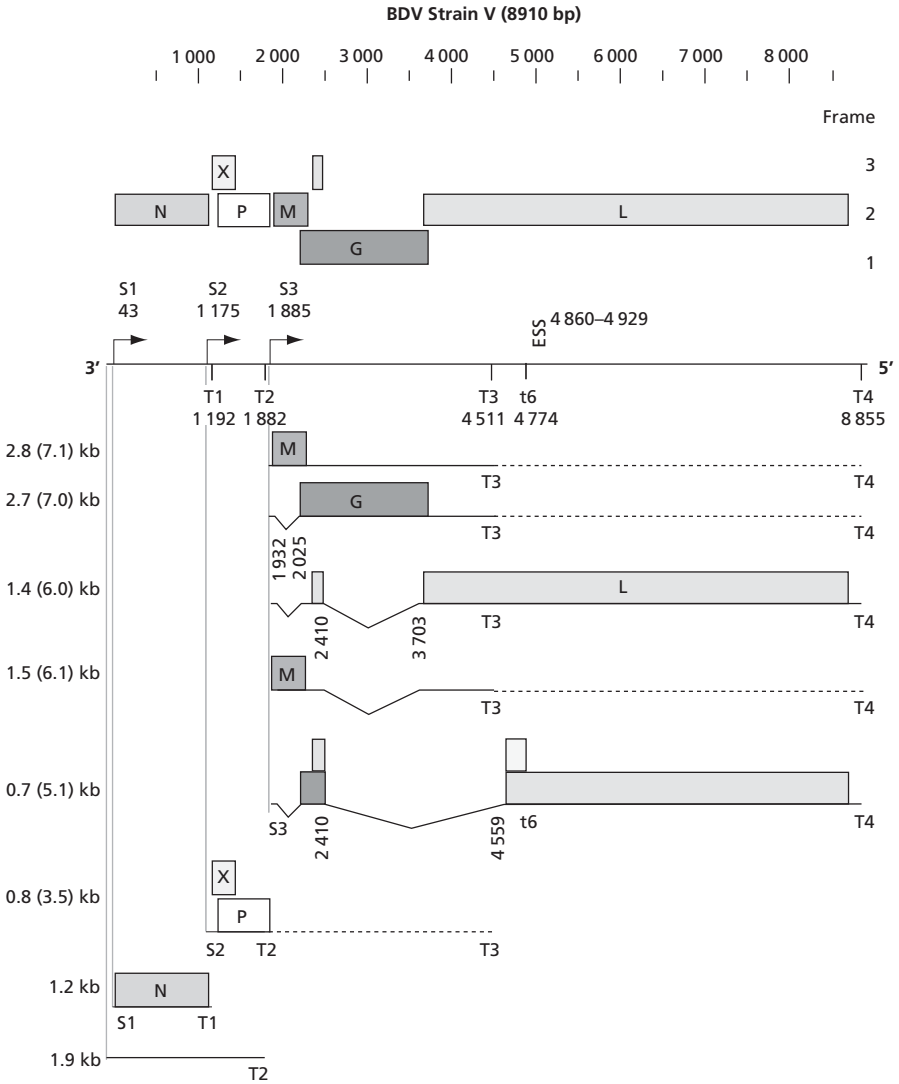

Figure 1 *BDV genomic map and transcripts. Abbreviations: S1 through S3, initiation sites of transcription; T1 through T4, and t6, termination sites of transcription. Readthrough at termination signals T2 and T3 is indicated by dashed lines; ESS, exon splicing suppressor.*

transcription of the (–) sense genome during replication (Schneemann et al. 1994). In other NNS RNA viruses the ratio or abundance of viral proteins during the replication cycle in the cell regulates the switch from transcription to production of full-length viral antigenome and genome from the same promoter sequences, rather than from different promoters. However, in vitro replication/transcription and reverse genetic systems are not yet established for BDV; thus, there are no direct data concerning how BDV regulates transcription and replication.

Transcription of the BDV genome results in the synthesis of at least six primary, polyadenylated, subgenomic RNAs with chain lengths of 0.8, 1.2, 1.9, 2.8, 3.5, and 7.1 kb (Briese et al. 1994; Cubitt et al. 1994a). The 7.1 kb RNA and 2.8 kb RNA are modified by splicing of two introns of approximately 0.1 and 1.3 kb to yield RNAs of 7.0/6.1/6.0 and 2.7/1.5/1.4 kb, respectively (Figure 1) (Cubitt et al. 1994b; Schneider et al. 1994b). The 7.1 or 7.0 kb RNAs can be further modified by alternative choice of the splice acceptor site of intron 2, generating a third intron of approximately 2.1 kb and yielding RNAs of 6.5 or 0.7 kb (or 6.6/0.8 kb if intron 1 is not spliced) (Tomonaga et al. 2000; Cubitt et al. 2001). The 1.9 kb RNA is fundamentally different from the other transcripts. It starts at the 3′ terminus of the genome rather than at the first transcription initiation signal, is not capped, and is only partly polyadenylated (Schneemann et al. 1994). Whether it represents an analog of leader-containing subgenomic RNAs found in other NNS RNA viruses or an abortive replication intermediate with a stop at the second termination signal is unknown.

The molar abundance of the individual BDV mRNAs in infected cultured cells and tissues resembles that of rhabdoviruses and paramyxoviruses, where transcription by the endogenous nucleocapsid-associated viral RNA polymerase complex occurs sequentially from the 3′ end of the genome following the order of the genes (Briese et al. 1994; Cubitt et al. 1994a). NNS RNA viruses typically contain signal sequences in the noncoding intergenic regions of the genome that specify transcriptional termination/polyadenylation and initiation by the viral polymerase complexes (Banerjee 1987). RNA circularization, followed by RT-PCR over the ligated ends and sequencing, revealed that BDV contains three semiconserved, U-rich initiation motifs that are unique to BDV, and four stop signals that, similar to other NNS RNA viruses, contain an A followed by six or seven U residues (Schneemann et al. 1994). However, the gene junctions are atypical for NNS RNA viruses as they cannot be clearly divided into discrete regions corresponding to a termination signal for one transcription unit, an intergenic region, and an initiation signal for the next transcription unit. The first and the second transcription units overlap, such that the second initiation signal, S2, lies upstream of the first termination signal, T1 (Figure 1). A similar organization is postulated to serve as an attenuation signal for control of polymerase expression in respiratory syncytial virus (Collins et al. 1987); however, in BDV, attenuation appears not to take place, as the two transcription units are expressed at similar levels (Briese et al. 1994). The second and third transcription units are separated by only two nucleotides, with the second termination signal, T2, fully contained within the third initiation signal, S3. The initiation signal S3 gives rise to two different primary transcripts: the first terminates at the third termination signal T3, whereas the second is expressed by readthrough of T3 and termination at T4 (Figure 1). Indeed, readthrough of T3 in BDV is essential for the expression of p190, the polymerase protein. Transcriptional readthrough may provide a means for regulating the expression of the BDV polymerase, a protein only needed in catalytic amounts. Consistent with this notion is the observation that levels of the 7.1 kb transcript are lower than those of the 2.8 kb transcript (Briese et al. 1994).

Splicing of BDV mRNAs

Splicing is an intriguing feature of BDV that allows for efficient use of its genome, controls the expression of three ORFs comprising the third transcription unit, and may have implications for neurotropism and pathogenesis. Introns are located at nucleotides (nt) 1932–2025 (intron 1) and 2410–3703 (intron 2) (Cubitt et al. 1994b; Schneider et al. 1994b) (Figure 1). Differential splicing and the potential for either termination or readthrough at the termination signal T3 allows for the expression of six additional RNAs (Schneider et al. 1994b). Differential splicing of the two introns regulates expression of the M, G, and L proteins. Splicing of intron 1 places the 13th amino acid (aa) residue of the M ORF in frame with a stop codon. Whereas this abrogates M expression, the resulting 13 aa minicistron facilitates G expression by ribosomal reinitiation (Schneider et al. 1997b). Preliminary data suggest that the 13 aa minicistron which facilitates G expression by ribosomal reinitiation also facilitates L expression. Splicing of intron 2 fuses 17 nt of an upstream, AUG-containing sequence with a continuous ORF comprising the remainder of the L coding sequence (nt 3703–8819) (Briese et al. 1994; Schneider et al. 1994b; Walker et al. 2000). Recently, an alternative splice acceptor site has been identified at nt 4559 (Figure 1) that is controlled by an exon splicing repressor downstream (Tomonaga et al. 2000). Splicing of intron 3 (nt 2410–4559) and transcriptional readthrough to t6 (Briese et al. 1994) may result in the expression of two additional BDV specified proteins (Tomonaga et al. 2000; Cubitt et al. 2001). In one potential product, the upstream L exon would be fused to a short ORF

terminating at t6 to yield an 8.4 kDa polypeptide. In the other, the N-terminal portion of G would be fused to the truncated L ORF to yield a 165 kDa polypeptide. Splice junctions associated with the three introns are homologous to mammalian splice junction consensus sequences and can be processed by the host-cell splicing machinery. However, the splice acceptor side at nt 4559 is not strictly conserved throughout sequenced BDV isolates; the lack of conservation in No/98 (Pleschka et al. 2001) indicates that potential protein products are not likely to be essential to the basic lifecycle of the virus.

Viral proteins

NUCLEOPROTEIN

The first ORF of the BDV antigenome codes for a protein of 40 kDa. Although participation in RNP complex formation and binding to RNA has yet to be demonstrated, its position in the viral genome, its size, and its relative abundance in infected cells suggests that it corresponds to the BDV nucleoprotein (N).

This protein, together with BDV P, comprises the soluble antigen (s antigen), a complex found in the noninfectious supernatant obtained after high-speed centrifugation of sonicated, infected brain, or cultured cells. The s antigen was a cornerstone for diagnosis of infection prior to the advent of molecular probes and recombinant proteins, and provided the first evidence for interaction of BDV proteins (von Sprockhoff 1956; Wagner et al. 1968; Ludwig et al. 1973; Haas et al. 1986; Bause-Niedrig et al. 1992).

The nucleoprotein exists as either a 40 kDa or a 38 kDa isoform. Whereas p40 uses the entire ORF, p38 initiates at the second in-frame AUG and lacks 13 aa at the amino terminus (Figure 2). It is unknown whether p38 and p40 are translated from a single transcript, although an RNA has been found that initiates downstream of S1 and encodes p38 (Pyper and Gartner 1997). Immunohistochemical and cell fractionation experiments with cells transfected for expression of p40 or p38 revealed that, whereas p40 is primarily nuclear, p38 is primarily cytoplasmic. This difference in the subcellular distribution of p40 and p38 reflects the presence in p40 of an amino terminal nuclear localization signal (NLS) ($_3$PKRRLVDDA$_{11}$) (Kobayashi et al. 1998; Pyper and Gartner 1997). The in vivo significance of the two isoforms of N is unknown. Both p38 and p40 bind the BDV phosphoprotein (P). P contains a potent NLS; thus, it is conceivable that the 38 kDa isoform may enter the nucleus through interaction with P. Interaction with P is facilitated by two motifs located in the N-terminal half of N (K_{51}–Y_{100}, and L_{131}–I_{158}; Figure 2) (Berg et al. 1998; Kobayashi et al. 2001). p38 and p40 also contain an internal leucine-rich nuclear export signal (NES) (L_{128}TELEISSIFSHCC$_{141}$) (Kobayashi et al. 2001) that overlaps with the P binding motif. It is hypothesized that the NLS-lacking p38 isoform of N, possibly in complex with mature RNPs, may redistribute to the cytosol after dissociation of bound P (Kobayashi et al. 2001).

X-PROTEIN

Unlike the first transcription unit, which is monocistronic and encodes only two isoforms of N, the second transcription unit is bicistronic and encodes two polypeptides expressed from different ORFs, X and P. X is expressed from an ORF that initiates upstream of P and overlaps with the P ORF in a +1 frame shift (Wehner et al. 1997). X and P interact in mammalian two-hybrid and coimmunoprecipitation experiments (Schwemmle et al. 1998). The site of binding on X has been localized to the N-terminal motif S_3DLRLTLLELVRRL$_{16}$ (Malik et al. 2000; Wolff et al. 2000). X is both nuclear and cytoplasmic. It has been suggested that nuclear localization of X is a result of its binding to P. Similarity of the leucine-rich N-terminal motif to NESs of several cellular and viral export proteins, such as HIV-1 Rev or PKI (see Figure 2, leucines underlined), led to speculation that X may mediate nucleocytoplasmic shuttling through its interaction with the viral RNP via P. However, recent data suggest that this motif functions as an NLS rather than an NES (Figure 2, R_6LTLLELVRRNGN$_{19}$ (Wolff et al. 2002)). X transport through the nuclear pore complex is mediated by direct binding to importin α. The role of X in the BDV lifecycle is unknown.

PHOSPHOPROTEIN

The phosphoprotein is expressed from the second ORF of the second transcription unit of the BDV genome. There is no evidence of splicing to eliminate the first AUG initiating translation of X (Briese et al. 1994; Cubitt et al. 1994a); thus, it is likely that P is expressed through a leaky scanning mechanism. The phosphoproteins of NNS RNA viruses are essential cofactors for virus transcription and replication. Their phosphorylation by cellular kinases influences the ability of phosphoproteins to form homomultimers, bind other viral proteins, and serve as transcriptional activators. Although there are no direct data concerning the function of P, it is postulated by analogy to be similar to other viral phosphoproteins. P contains two strong NLSs at its N and C termini (Figure 2) (Shoya et al. 1998; Schwemmle et al. 1999b). Mammalian two-hybrid and coimmunoprecipitation experiments indicate that P interacts with itself, X, and N. Analysis of P truncation mutants led to the identification of three nonoverlapping regions important for homo-oligomerization (aa 135–172), binding to X (aa 33–115), and to N (aa 197–201) (Figure 2) (Schwemmle et al. 1998).

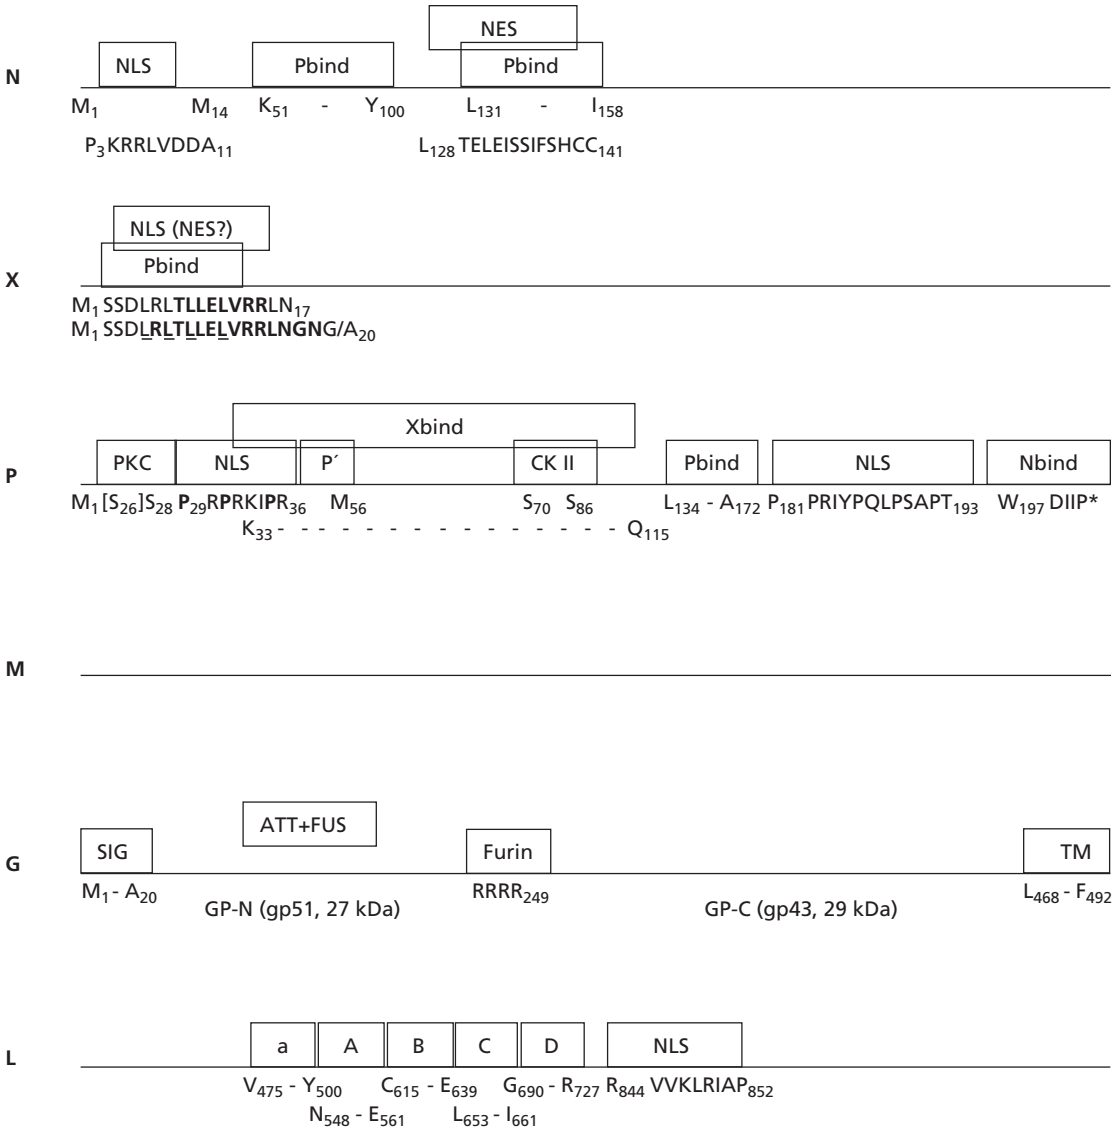

Figure 2 *Functional motifs identified in BDV proteins. Abbreviations: a, A, B, C, D, conserved L-polymerase motifs; ATT + FUS, attachment and fusion domain; CK II, casein kinase II phosphorylation; Furin, Furin cleavage site; M1 and M14 in N, and M1 and M56 in P indicate start sites of p40 and p38, or P and P', respectively; Nbind, site of interaction with N; NES, nuclear export signal; NLS, nuclear localization signal; Pbind, site of interaction with P; PKCϵ, protein kinase Cϵ phosphorylation; SIG, signal peptide; TM, transmembrane domain; Xbind, site of interaction with X.*

Investigation of the phosphorylation sites of P revealed a complex phosphorylation pattern that is unusual for NNS RNA viruses. P is phosphorylated predominantly by protein kinase Cϵ (PKCϵ) and, to a lesser extent, by casein kinase II (CK II). Peptide mapping studies identified Ser28 (and Ser26, which is not present in all strains) as site(s) for PKCϵ, and Ser70 and Ser86 as sites for CK II phosphorylation (Schwemmle et al. 1997). In other viral systems, sequential phosphorylation by different kinases may be associated with conformational changes that influence protein–protein interactions (Barik and Banerjee 1992). Whereas the PKCϵ phosphorylation site(s) of P overlap with the NLS, the CK II phosphorylation sites overlap with the region of interaction with X (Figure 2). Thus, it is conceivable that the status of P phosphorylation may influence nuclear trafficking of P (and possibly X through its interaction with P). PKCϵ is highly concentrated in limbic circuitry (Saito et al. 1993). This observation is intriguing, given the limbic distribution of BDV, and suggests that phosphorylation events may be important in BDV neurotropism.

MATRIX PROTEIN

The first ORF of the third transcription unit predicts a protein with a molecular weight of 16 kDa (p16, M). This protein was characterized as a viral product prior to

the advent of genetic analysis of BDV when a 14.5 kDa protein was isolated from the brains of neonatally infected rats (Schädler et al. 1985). Later, protein microsequencing identified this protein as the product of the 16 kDa ORF (Kliche et al. 1994). Early studies indicated oligosaccharide modification of extracted protein, and a neutralizing activity of p16-specific antibodies led to the speculation that p16 might be an unusual, glycosylated matrix protein (Kliche et al. 1994; Hatalski et al. 1995; Stoyloff et al. 1997). However, more recent work indicates that p16 is a nonglycosylated matrix protein (Kraus et al. 2001). In light of these data, the neutralizing activity of p16-specific antibodies may represent reactivity with RNPs, which are thought to be involved in the spread of BDV during infection (Cubitt and de la Torre 1994; Gosztonyi et al. 1993).

GLYCOPROTEIN

The second ORF of the third transcription unit predicts a protein with a molecular weight of 57 kDa. Posttranslational modification by N-glycosylation with high-mannose oligosaccharides yields a full-length type 1 membrane protein of 94 kDa (G, gp94) (Schneider et al. 1997a; Richt et al. 1998; Kiermayer et al. 2002) that is proteolytically processed by the cellular protease furin (Richt et al. 1998). Carboxyterminal cleavage of arginine$_{249}$ yields two fragments, GP-N (27 kDa nonglycosylated) and GP-C (29 kDa nonglycosylated) (Kiermayer et al. 2002; Richt et al. 1998) (Figure 2). Whereas precursor gp94 accumulates in the endoplasmic reticulum, the GP-C product is transferred to the cellular membrane, anchored by its C-terminal transmembrane domain. Both gp94 and glycosylated GP-C (43 kDa, gp43) are incorporated into infectious particles (Gonzalez-Dunia et al. 1997). The extensively glycosylated GP-N product (51 kDa, gp51) was recently demonstrated in infected cells and infectious particles (Kiermayer et al. 2002). Analysis of the N-glycans in gp43 and gp51 revealed maturation of the oligosaccharide chains. Whereas precursor gp94 carries only high-mannose glycans, gp43 and gp51 both contain a mixture of high-mannose and complex type glycans (Kiermayer et al. 2002).

In other viral systems glycoproteins typically mediate attachment and entry, and it has been suggested that BDV enters the cell through endocytosis followed by membrane fusion in the acidic environment of the endosome (Gonzalez-Dunia et al. 1998). Several lines of evidence indicate a role for G in BDV attachment and entry. Neutralization activity of sera from infected animals is reduced following immunoadsorption with gp94 protein; preincubation of susceptible cells with G protein interferes with infectivity (Schneider et al. 1997a); and sera raised against a bacterially expressed, truncated protein (starting at M_{150}) neutralizes BDV (Gonzalez-Dunia et al. 1997). Protease inhibitor studies indicate that cleavage of the precursor gp94 is essential for infectivity (Richt et al. 1998). Pseudotyping experiments implicate the N-terminal portion of the BDV G protein in attachment and entry (Perez et al. 2001). In view of recent data indicating the presence of GP-N in virions (Kiermayer et al. 2002), it seems likely that critical residues are positioned C-terminal of M_{150}.

Although G may be expressed from unspliced transcripts by leaky ribosomal scanning, intron 1 spliced transcripts are more likely to serve as messages for G in vivo (Schneider et al. 1997b).

POLYMERASE

The most 5′ gene of BDV occupies more than half of the BDV genome and is thought to represent the viral RNA-dependent RNA polymerase, analogous to other NNS RNA virus L polymerases. A continuous ORF with a coding capacity of 190 kDa is formed by RNA splicing of intron 2, which fuses a small upstream ORF to the large downstream ORF (Briese et al. 1994; Schneider et al. 1994b). The product of this splicing event is considered to represent the active BDV polymerase, though no functional data are currently available (Walker et al. 2000). The protein contains the known conserved L-polymerase motifs (Briese et al. 1994; Cubitt et al. 1994a) (Figure 2) and, similar to other L polymerases, it interacts with P and is phosphorylated by cellular kinases (Walker et al. 2000). The protein localizes to the nuclear compartment of infected cells (Walker et al. 2000), mediated by a strong NLS mapped to a R_{844}VVKLRIAP$_{852}$ motif in the middle of the ORF shortly after the conserved L polymerase motif D (Walker and Lipkin 2002).

PATHOGENESIS AND EPIDEMIOLOGY OF BDV

Hosts and epidemiology

A syndrome of progressive meningoencephalitis of horses and sheep consistent with BDV infection (von Sind 1767) was recognized 100 years before the disease received its name from an equine outbreak near the town Borna in Germany. Although this clinical pattern is still considered to represent classic Borna disease (BD), infection may also result in asymptomatic carrier status, subtle disturbances in learning and memory, profound disorders of behavior and movement (Narayan et al. 1983a; Carbone et al. 1989, 1991a; Rott and Becht 1995), or death. Emerging epidemiologic data, including reports of asymptomatic, naturally infected animals (Matthias 1954; Ihlenburg and Brehmer 1964; Lange et al. 1987; Kao et al. 1993; Nakamura et al. 1995, 1996; Bahmani et al. 1996; Hagiwara et al. 1997a, 2001; Reeves et al. 1998; Berg et al. 1999, 2001; Nishino et al.

1999; Yamaguchi et al. 1999; Dauphin et al. 2001; Helps et al. 2001; Horii et al. 2001; Vahlenkamp et al. 2002; Inoue et al. 2002; Yilmaz et al. 2002), suggest that the host range and geographic distribution of BDV are larger than previously appreciated (Table 1). Natural infection has been reported in a wide variety of hosts, including horses, donkeys, sheep, cattle, dogs, cats, rabbits, lynxes, foxes, and birds. Experimental infection has been achieved in many of these species, and also in rodents and primates. Whether BDV naturally infects humans remains controversial; however, there is consensus that all warmblooded animals are likely to be susceptible to infection. Although Central Europe has the highest reported prevalence of Borna disease, natural infection has been described throughout Europe, in Asia, and in North America. It is unclear whether the apparent increase in host and geographic range of BDV is due to spread of the virus, or enhanced awareness of the agent and improved diagnostic reagents.

Neither the reservoir nor the mode of transmission of natural infection is known. Natural infection of horses and sheep is typically sporadic and peaks in the spring months; epidemics of disease are infrequent (reviewed in Dürrwald and Ludwig 1997). An olfactory route of transmission has been proposed because intranasal infection is efficient and the olfactory bulbs of naturally infected horses show inflammation and edema early in the course of disease (Joest and Degen 1911; Ludwig et al. 1988). One outbreak in a zoo has been attributed to inadvertent inoculation of BDV during vaccine administration (H. Müller, personal communication). Experimental infection of neonatal rats results in virus persistence and is associated with the presence of viral gene products in saliva, urine, and feces (Sierra-Honigmann et al. 1993). Such secreta/excreta are known to be important in the transmission of other pathogenic viruses (for example, lymphocytic choriomeningitis virus, hantaviruses). Normal adult rats housed in cages separate from but adjacent to those of neonatally infected rats can become infected, suggesting the possibility of aerosol transmission (M. Hornig, M. V. Solbrig, and T. Briese, personal communication). Reports of BDV nucleic acid and proteins in peripheral blood mononuclear cells (PBMC) also indicate a potential for hematogenous transmission (Sierra-Honigmann et al. 1993; Rubin et al. 1995). The observations that rodents can be persistently infected with BDV and excrete virus suggest that they have the potential to serve as both natural reservoirs and vectors for virus dissemination. However, naturally infected rodents have not been found (Tsujimura et al. 1999; Hagiwara et al. 2001); thus, the significance of rodents for the transmission of BDV to other domesticated animals and humans remains speculative. An alternative avian reservoir is suggested by studies indicating the presence of BDV nucleic acids in the feces of wild mallards and jackdaws (Berg et al. 2001).

Natural infections

Although infection may be asymptomatic, symptomatic disease typically follows a predictable course. Clinical signs at the onset of disease in horses and sheep are nonspecific: excited or depressed behavior, hyperthermia, anorexia, jaundice, constipation, and colic (Rott and Becht 1995). Classic disease becomes apparent within 1–2 weeks. Animals maintain an upright, wide-based stance, with the head extended. Repetitive behaviors are common and may include vacuous chewing, circular ambulation, and running into obstacles. In the terminal phases of disease, horses become paretic. A distinctive decubitus posture associated with paddling movements of the legs has been described. Frequently, in late disease, the virus migrates centrifugally along the optic nerve to cause retinopathy and visual impairment. Acute mortality may be as high as 80–100 percent in horses and 50 percent in sheep (Rott and Becht 1995). Sheep that survive may have permanent neurologic deficits. Recurrence of acute disease has been described in sheep (Heinig 1969). Natural symptomatic infection with a fatal outcome has also been reported in cattle (Bode et al. 1994; Caplazi et al. 1994), cats (Lundgren and Ludwig 1993; Lundgren et al. 1995a, b; Nakamura et al. 1999b), rabbits (Metzler et al. 1978), and dogs (Weissenbock et al. 1998; Okamoto et al. 2002). Epidemics of paresis in ostriches were attributed to BDV infection; however, these data have not been confirmed (Malkinson et al. 1995).

Viral persistence without apparent disease has been described in naturally infected horses (Ihlenburg and Brehmer 1964; Lange et al. 1987; Nakamura et al. 1995; Berg et al. 1999; Hagiwara et al. 2002), sheep (Matthias 1954; Hagiwara et al. 1997a; Vahlenkamp et al. 2002), and cats (Nakamura et al. 1996; Reeves et al. 1998; Nishino et al. 1999; Helps et al. 2001; Horii et al. 2001) in Europe and Asia. There is one report indicating subclinical infection of horses in North America (Kao et al. 1993). Vertical transmission of BDV has been described in horses (Hagiwara et al. 2000).

Experimental models of bornavirus infection

A wide range of animal species has been experimentally infected with BDV. Rats (Nitzschke 1963; Hirano et al. 1983; Narayan et al. 1983a), mice (Kao et al. 1984; Rubin et al. 1993; Hallensleben et al. 1998), rabbits (Zwick and Seifried 1925; Krey et al. 1979a, b), guinea pigs (Zwick and Seifried 1925), gerbils (Nakamura et al. 1999a; Watanabe et al. 2001), tree shrews (Sprankel et al. 1978), rhesus monkeys (Zwick et al. 1927; Pette and Környey 1935; Cervos-Navarro et al. 1981; Stitz et al. 1981; Krey et al. 1982), and chickens (Zwick et al. 1926; Ludwig et al. 1988) are all susceptible to classic disease; however, the

incubation period, mortality, and severity of disease vary considerably between species, between strains within a species, and depend on the immune status of the host. Whereas, in immunocompetent adult hosts, infection results in dramatic immune-mediated meningoencephalitis consistent with the classic syndrome observed in naturally infected horses and sheep, animals tolerant of infection owing to immature or compromised immune systems have a more subtle course.

ADULT RAT MODEL

Susceptibility to disease varies with the host rat strain. Wistar rats and black-hooded (BH) rats can be productively infected but have less severe disease than Lewis rats, a strain with a lesion in the hypothalamopituitary–adrenal axis associated with enhanced susceptibility to immune-mediated disorders, such as experimental allergic encephalomyelitis and adjuvant-induced arthritis (Cizza and Sternberg 1994; Sternberg et al. 1990). One report found that resistance to BD was inherited as a dominant trait in Lewis and BH hybrids that was independent of major histocompatibility complex (MHC) genes (Herzog et al. 1991). The virulence of viral strains for rats may be enhanced by serial passage of the virus in rat brain (Nitzschke 1963).

Infection is most rapidly achieved with intracranial and intranasal inoculations. Nonetheless, any route of

inoculation that allows virus access to nerve terminals (for example, intramuscular, intraperitoneal, or footpad injection) ultimately results in central nervous system (CNS) infection and classic disease. Viremia is unlikely to play a significant role in BDV dissemination and pathogenesis. Although viral gene products have been found in PBMCs of infected animals (Steinbach 1994), intravascular inoculation only infrequently results in productive infection. Several observations indicate that BDV disseminates primarily via neural networks: (1) viral proteins and nucleic acids can be traced centripetally and transsynaptically after olfactory, ophthalmic, or intraperitoneal inoculation (Carbone et al. 1987; Morales et al. 1988); (2) the onset of disease is delayed with distance of the inoculation site to the CNS (Carbone et al. 1987); and (3) migration of virus to the CNS after footpad infection can be prevented by sciatic nerve transection (Carbone et al. 1987). Irrespective of the route of inoculation, clinical disease begins coincidentally with the appearance of viral proteins in hippocampal neurons and the onset of meningitis (Carbone et al. 1987; Richt et al. 1989). It has been proposed that BDV, like rabies virus, is likely to spread as an RNP complex within neural networks (Gosztonyi et al. 1993). Although structures consistent with RNPs have been described in neurons of experimentally infected animals (Cervos-Navarro et al. 1981; Sasaki and Ludwig 1993), the form of disseminating virus is unknown.

Infection of adult Lewis rats produces a prominent neurobehavioral disorder and is characterized by pronounced immunopathology. In the acute phase (4–8 weeks post infection), cellular infiltrates ($CD4^+$ and $CD8^+$ T cells, natural killer (NK) cells, and macrophages) and Th1-type cytokines are prominent in perivascular and parenchymal regions of CNS; in the chronic phase (15 weeks post-infection and beyond), a decline in infiltrates is accompanied by an increase in Th2-type cytokines and a shift to a humoral immune response (Hatalski et al. 1998a). Although antibodies to N and P generated during the acute phase of disease are nonneutralizing (Furrer et al. 2001), antibodies with neutralizing capacity increase dramatically after the acute phase (Hatalski et al. 1995) and probably participate in restriction of the virus to neural tissues (Stitz et al. 1998a). Mechanisms contributing to viral persistence are as yet uncertain. Altered viral gene expression is an unlikely explanation as there is little substantive change in CNS over the course of disease in viral titers (Narayan et al. 1983b; Carbone et al. 1987), transcripts coding for BDV proteins, or levels of BDV N and P proteins (Hatalski 1996). Modulation of immune responses as BD progresses to the chronic phase may exert some influence on BDV persistence.

The distinct clinical and behavioral features of the immune-mediated adult rat model closely parallel the CNS pathology of the acute and chronic phases. In the acute phase, coinciding with monocyte infiltration in CNS regions of early viral burden, such as the hippocampus, amygdala, and other limbic structures (Carbone et al. 1987), animals demonstrate exaggerated startle responses and hyperactivity. As animals enter the chronic phase of infection, high-grade stereotyped motor behaviors (continuous repetition of behavioral elements, including sniffing, chewing, scratching, grooming, and self-biting), dyskinesias, dystonias, and flexed seated postures appear (Solbrig et al. 1994), in parallel with the spread of virus throughout limbic and prefrontal circuits. Up to 10 percent of animals become obese, achieving body weights up to 300 percent of normal (Ludwig et al. 1988).

Disorders of movement and behavior in adult-infected rats are associated with dysfunction in dopamine (DA) circuits (Solbrig et al. 1994, 1995, 1996a, b, 1998), as seen in many neuropsychiatric disorders (Cooper et al. 1991; Kane and Marder 1993; Anderson 1994; Hamner and Diamond 1996; Kelsoe et al. 1996; Partonen 1996; Ernst et al. 1997), and may be further linked to serotonin (5HT) abnormalities (Solbrig et al. 1995). Enhanced sensitivity of central DA systems of adult-infected BD animals to DA agonists, antagonists, and DA reuptake inhibitors is observed. Administration of the mixed-acting DA agonist dextroamphetamine (Solbrig et al. 1994), or of cocaine, a DA reuptake inhibitor, to adult-infected rats elicits increased locomotor and stereotypic behavior, indicating dose-dependent potentiation of DA neurotransmission (Solbrig et al. 1998). Low presynaptic autoreceptor doses of the direct DA agonist apomorphine reduce hyperactivity, whereas higher doses increase locomotion. Both pre- and postsynaptic sites of the DA transmitter system appear to be damaged in striatum: DA reuptake sites, as measured by mazindol binding, are reduced in caudate-putamen (Solbrig et al. 1998) and nucleus accumbens (Solbrig et al. 1996b); and postsynaptic D2, but not D1, receptor binding is markedly reduced in caudate-putamen, whereas D2 and D3 receptor binding is reduced in nucleus accumbens (Solbrig et al. 1994, 1996a, b). In contrast, postsynaptic DA receptors (D1, D2, D3) remain intact in prefrontal cortex (Solbrig et al. 1996a). Further support for D2-selective losses and resultant D1 hypersensitivity as mediators of neurobehavioral disturbances in adult BD is found in the ability to reverse locomotor hyperactivity through the administration of D1 receptor blocking agents, such as the D1 antagonist SCH23390, or clozapine, an atypical antipsychotic with mixed D1, D2, D3, and D4 antagonist activity, but not through the administration of D2-selective antagonists (e.g. raclopride) (Solbrig et al. 1994).

Neurochemical studies further support a lesion in DA transmission consistent with partial DA deafferentation and compensatory metabolic hyperactivity in nigrostriatal and mesolimbic DA systems. Decreases in DA levels exceed those in dihydroxyphenylacetic acid (DOPAC, the major metabolite of DA) levels in high

performance liquid chromatography (HPLC) analysis of tissues from striatum, nucleus accumbens, and olfactory tubercle (Solbrig et al. 1994), whereas in prefrontal cortex marked increases are noted in DOPAC (Solbrig et al. 1996a). Depletion of tyrosine hydroxylase (TH)-immunoreactive cells in substantia nigra, ventral tegmental area (Solbrig et al. 1994), and striatum (Solbrig et al. 2000), and a decrease TH protein content in striatum but not in substantia nigra pars compacta, are nonetheless accompanied by an increase in TH functional activity (Solbrig et al. 2000). Increased gene expression of neurotrophic factors that support the growth of DA-producing cells in vitro, including BDNF, NT-3, NT-4, and CNTF, may also contribute to the sensitivity to DA agonist action in adult BD (Solbrig et al. 2000).

Additional neuromodulator abnormalities are also noted in the adult model. The expression of genes for neuromodulatory substances and their associated synthesizing enzymes, including somatostatin, cholecystokinin, and glutamic acid decarboxylase, is greatly reduced during the acute phase and recovers toward normal in the chronic phase of adult BD (Lipkin et al. 1988). The cholinergic system, a major participant in sensorimotor processing, learning, and memory, is similarly affected, with a decrease in choline acetyltransferase-positive fibers as early as day 6 post-infection, progressing to nearly complete loss of these fibers in hippocampus and neocortex by day 15 (Gies et al. 1998). Preliminary work on the dysregulation of 5HT and norepinephrine (NE) systems suggests metabolic hyperactivity of 5HT, with a modest increase in the metabolite 5-hydroxyindoleacetic acid in striatum, and of NE, as evidenced by a small increase in the NE metabolite, 3-methoxy-4-hydroxyphenethyleneglycol, in prefrontal and anterior cingulate cortex regions (Solbrig et al. 1995). These changes may reflect compensatory upregulation or heterotypic sprouting following partial loss of DA afferents to these brain regions. Selective effects of BDV on 5HT and NE pre- or post-synaptic receptors have not yet been investigated. Pharmacologic and neurotransmitter-specific molecular probes have also been used to characterize endogenous opioid systems in the adult rat model. Infected animals respond abnormally to the opiate antagonist naloxone, with hyperkinesis and seizures, and also demonstrate increases in striatal preproenkephalin mRNA at 14 and 21 days (Fu et al. 1993b), and 6 weeks after BDV infection (Solbrig et al. 2002a). BDV and met-enkephalin immunoreactivity also coincide in a high percentage of cells (Solbrig et al. 2002a). Induction of the enkephalin system in adult BD may relate to increased levels of phosphorylated cyclic AMP response element binding (phosphoCREB) protein through activation by BDV of the mitogen-activated protein (MAP) kinase pathway, thus stimulating transcription factors that regulate enkephalin expression in striatum (Konradi et al. 1993). However, the mechanisms by which these changes in endogenous opioid systems occur are unclear. The marked CNS inflammation in adult-infected rats confounds the role of direct effects of the virus, virus effects on resident cells of the CNS, and cellular immune responses to viral gene products in the production of monoamine, cholinergic, and opiatergic dysfunction in BD.

NEONATAL RAT MODEL

The neonatal rat model does not show overt immunopathology; instead, despite a high virus load in the brain and lifelong persistence, animals infected within the first 12 h of life develop a milder behavioral syndrome and restricted neuropathology that may provide a more intriguing model for neuropsychiatric disorders. The cerebellar and hippocampal dysgenesis observed in neonatally infected animals is consistent with the more subtle neurodevelopmental abnormalities reported by some investigators in autism (Kemper and Bauman 1993), schizophrenia (Altshuler et al. 1987; Fish et al. 1992), and affective disorders (Soares and Mann 1997). Neonatally infected animals display a wide range of physiologic and neurobehavioral disturbances. They are smaller than uninfected littermates (Carbone et al. 1991b; Bautista et al. 1994), with no demonstrable alteration of glucose, growth hormone, or insulin-like growth factor-1 (Bautista et al. 1994) or amount of food ingested (Bautista et al. 1995); display an enhanced preference for salt solutions; and exhibit altered circadian rhythms (Bautista et al. 1994). Behavioral and cognitive changes in rats infected in the neonatal period include abnormal early locomotor development (Hornig et al. 1999), spatial and aversive learning deficits (Dittrich et al. 1989; Rubin et al. 1999), increased motor activity (Bautista et al. 1994; Hornig et al. 1999), abnormal anxiety responses (Dittrich et al. 1989; Hornig et al. 1999; Pletnikov et al. 1999a), stereotypic behaviors (Hornig et al. 1999), and reduced initiation of, and response to, nondominance-related play interactions (Pletnikov et al. 1999b). Thus, the neuropathologic, physiologic, and neurobehavioral features of BDV infection of neonates indicate that it not only provides a useful model for exploring the mechanisms by which viral and immune factors may damage developing neurocircuitry, but also has significant links to the range of biologic, neurostructural, locomotor, cognitive, and social deficits observed in a wide range of human neuropsychiatric illnesses.

CNS dysfunction in neonatally infected animals has been proposed to be linked to direct viral effects on morphogenesis of the hippocampus and cerebellum, two structures that in rodents continue to mature postnatally. Although overall architecture is maintained, granule cells of the dentate gyrus (Hornig et al. 1999; Rubin et al. 1999) and Purkinje cells of the cerebellum are lost (Eisenman et al. 1999; Hornig et al. 1999) through apoptosis (Hornig et al. 1999). The extent of neuronal loss in

the dentate gyrus is correlated with the severity of spatial learning and memory deficiencies in neonatally infected Lewis rats (Rubin et al. 1999). Testing of cerebellar function demonstrates deficits in motor coordination and postural stability (Hornig et al. 1999; Pletnikov et al. 2001), consistent with Purkinje cell losses. Further studies are needed to evaluate the mechanisms by which early postnatal exposure to BDV induces apoptotic losses and functional damage in cerebellar and limbic circuitry.
